The size and output characteristics of aerosols generated from such liquids depend on their physicochemical properties (density, surface tension, viscosity) in conjunction with the nebulizer design and operating conditions. Empirical and semiempirical formulas predict that the droplet size of the aerosols is proportional to surface tension and inversely related to viscosity, whereas the effect of density, over the concentration range normally encountered, is negligible. The filtering effects of the baffles and solvent evaporation may modify the secondary aerosol produced, but studies (32, 37, 45, 46) have found viscosity to be a major determinant of aerosol size and output characteristics. High-viscosity fluids offer greater resistance to the integral fountain-disintegration process, thereby producing not only lower output but also larger droplets. Gershenzon and Eknadosyants (14) noted higher droplet outputs with lower viscosity fluids, whereas Boucher and Kreuter (32) reported that it was difficult to ultrasonically aerosolize fluids with viscosities exceeding 10 cP. Gershenzon and Eknadosyants (14) stated that the atomization rate for a wide range of fluids (except water) is given by the proportionality of A^2 to $\pi p/\eta\sigma$, where A is the atomization rate, p is the liquid vapor pressure, η is the viscosity, and σ is the surface tension.

Il'in and Eknadosyants (15) suggested that the dynamic viscosity coefficient was the most important property determining the nebulization rate. The rate of nebulization for solutions of tyloxapol or *N*-acetyl-L-cysteine decreased progressively as the solution viscosity increased. When certain oily and viscous liquids (e.g., Lipiodal®; a radio-opaque diagnostic agent) were nebulized, a fountain of liquid was generated, although this did not disintegrate to produce an aerosol. Similar results were reported by McCallion et al. (37), who compared a range of different model fluids, finding that ultrasonic nebulizers could not efficiently atomize the more viscous liquids and tended to produce poor total fluid outputs. Furthermore, when the fluid viscosity increased, larger droplets were generated.

Surface tension is also important because it represents the force resisting the formation of new surfaces. These forces tend to impair atomization by opposing any distortion or irregularity on the liquid surface, thereby delaying the onset of fountain formation. In suspension formulations, surfactants may be present as suspending agents. Reduction in liquid surface tension, through the addition of these agents, may decrease nebulization rate. This may be attributed to reduction in capillary wavelength, causing an increase in threshold amplitude (45) or through their influence on the diffusion of gas into cavitation bubbles (47). When a range of pharmaceutically relevant surfactant systems was nebulized, an inverse relationship was found between droplet size and surface tension over the entire concentration range investigated or to a peak value (33). There was no relationship between this peak value and a specific surface tension or the critical micelle concentration. In most cases, the total fluid output was unchanged.

Most nebulizer formulations are solutions, but a few corticosteroid suspension formulations have been marketed. In general, ultrasonic nebulizers are less efficient and more variable in delivering suspensions than are air-jet nebulizers. Although soluble radiopharmaceuticals may be more appropriate for delivery from ultrasonic nebulizers (48), Lin et al. (49) successfully used an ultrasonic nebulizer to deliver radiolabeled sulfur and tin colloids for lung imaging. McCallion et al. (50) nebulized a range of latex sphere suspensions in air-jet and ultrasonic nebulizers. No correlation was found between the size of the suspended spheres and the size distribution of the nebulized droplets. Higher outputs of smaller spheres were reported, with a concentrating effect occurring in the residual volume. The ultrasonic nebulizer studied was less efficient than the jet nebulizers, degrading some of the larger spheres and being unable to atomize suspended spheres of a specific size range.

Nebulizers, particularly air-jet devices, have been studied extensively for the delivery of liposomes to the lung (e.g., 51, 52). Because in ultrasonic nebulizers, the temperature of fluid in the reservoir is raised during use, they have generally been avoided for delivering liposomes, which exhibit temperature-dependent drug release. Barber and Shek (53) reported that egg phosphatidylcholine (egg PC) liposomes with a mean size of 281 nm or smaller were stable to nebulization in a DeVilbiss Ultra-Neb 99[®] ultrasonic nebulizer. However, dipalmitoylphosphatidylcholine liposomes of 499 nm increased in size within the nebulizer reservoir, suggesting fusion of vesicles, which could result in loss of entrapped hydrophilic materials. A later study (54) showed that the size of large multilamellar egg PC

liposomes remaining in a Medix Electronic nebulizer decreased markedly during nebulization, suggesting vesicle disruption, which was reduced by including cholesterol in the formulations.

Ultrasonic nebulizers are less suitable than jet nebulizers for delivery of proteins to the airways because of their thermal sensitivity. In a comparison of eight air-jet and two ultrasonic nebulizers, all air-jet nebulizers maintained the enzymatic activity of rhDNase in both the collected aerosol and the residual volume (31). With the ultrasonic nebulizers, some thermal denaturation of the enzyme was evident toward the end of the nebulization period when the liquid volume was minimal and its temperature highest. The maximum temperature of the rhDNase solution was 58°C, which was near the thermal transition temperature (approximately 65°C) of the enzyme (31).

Ip et al. (55) investigated DeVilbiss Aerosonic[®], Mountain Medical Microstat[®], and Medix Electronic[®] ultrasonic nebulizers for the delivery of recombinant consensus α -interferon. The extent of protein aggregation was governed by the type of nebulizer used with, the Easimist causing the least and Microstat the most aggregation. This was related to the increase in temperature and could be minimized by cooling the nebulizer solution during use. The Aerosonic[®] nebulizer completely inactivated lactate dehydrogenase after 20 min (38). The profile of inactivation differed from that of an air-jet nebulizer and was associated both with the temperature increase of the nebulizer fluid and the aerosol production. The activity of the enzyme was almost completely retained if Tween 80 or PEG 8000 was included in the nebulizer fluid.

GUIDELINES AND STANDARDIZATION FOR THE USE OF NEBULIZERS

The British Thoracic Society Nebulizer Project Group published a set of guidelines for nebulizer treatment (18). Their findings relating to ultrasonic devices are summarized as follows.

1. The aim of treatment is to deliver a therapeutic dose of the drug as an aerosol in the form of respirable particles within 5–10 min.
2. Nebulizers are useful when large doses of drug are to be inhaled by patients too ill to use alternative devices and when drugs are not available for delivery from pMDIs and DPIs.
3. Nebulizers are generally used to treat acute exacerbations of asthma or chronic obstructive pulmonary

disease. Other indications include long-term bronchodilator treatment of chronic airflow obstruction; prophylactic treatment for asthma; antimicrobial drugs for cystic fibrosis, bronchiectasis, and HIV/AIDS; and symptomatic relief in palliative care.

4. When drugs other than bronchodilators are being nebulized, equipment known to provide a suitable output should be used, and specific instructions should be given to patients. Such treatment should be supervised by hospital specialists.
5. Nebulization times for bronchodilators should be less than 10 min. Nebulization times and correct operation of devices should be familiar to the patients.

Convenience and patient preference determine whether a mouthpiece or face mask is used.

Currently, there are no *U.S. Pharmacopeia* or *European Pharmacopoeia* standard tests for characterizing the output of respiratory solutions or suspensions generated by air-jet or ultrasonic nebulizers. If nebulizers are to truly compete with pMDIs and DPIs, standardization of methods to measure dead volume, quantity of aerosol emitted from the device, nebulization times, and the size distribution of nebulized clouds is a logical and fundamental requirement.

UNIT PROCESSES IN PHARMACY— THE OPERATIONS

Anthony J. Hickey

University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, U.S.A.

David Ganderton

Vectura Ltd., Bath, United Kingdom

INTRODUCTION

The fundamentals of unit processes have been described elsewhere (1, 2). The following is a summary of the major operations. Although it is broad in scope, the abbreviated form of this article has resulted in selected omissions. References are given, wherever possible, to make up for this deficiency.

EVAPORATION AND DISTILLATION

Evaporation

The term evaporation, in the pharmaceutical industry, is primarily associated with the removal of water and other solvents by boiling in batch processes.

Heat transfer to boiling liquids in an evaporator

The heat required to boil a liquid in an evaporator is usually transferred from a heating fluid, such as steam or hot water, across the wall of a jacket or tube in or around which the liquid boils. A qualitative discussion of the methods used to secure high rates of heat flow can be used on Equation (1),

$$Q = UA \Delta T \quad (1)$$

where Q is the rate of heat flow, U is the overall heat transfer coefficient, A is the area over which heat is transferred, and ΔT is the difference in temperature between the fluids.

Other factors described by Eq. 1 are the area of the heat transfer surfaces, which should be as large as possible, and the temperature difference between the heating surface and the boiling liquid. As long as the critical heat flux is not exceeded, the latter also should be large.

The physical properties of solution and liquids

A number of physical factors, which are inter-related, are relevant to the study of evaporation. For a given heating

fluid, the temperature difference across the wall of an evaporator is determined by the boiling temperature, a variable controlled by the external pressure and the concentration of the solute in the solution. The boiling temperature and the solute concentration both influence the viscosity of the solution, a factor which greatly affects the heat transfer coefficient. The boiling temperature also determines the solubility of dissolved constituents and the degree of concentration which can be carried out without separation of solids.

The effect of heat on the active constituents of a solution: The thermal stability of components of a solution may determine the type of evaporator to be used and the conditions of its operation. If a simple solution contains a hydrolyzable material and the rate of its degradation during evaporation depends on its concentration at any time, an exponential relation between the remaining fraction, F , and the time, t , characteristic of a first-order reaction, is obtained, as shown in Eq. 2.

$$F = e^{-kt} \quad (2)$$

The dependence of the reaction velocity constant, k , on the absolute temperature, T , is expressed by Eq. 3,

$$k = Ae^{-B/T} \quad (3)$$

where A and B are constants characteristic of the reaction. Thus, at temperatures T_1 , T_2 , and T_3 , where $T_1 > T_2 > T_3$, the relation between the remaining fraction and the time of heating becomes clear, as shown in Fig. 1. This indicates the importance of the temperature and time of heating. If the latter can be shortened, the temperature of evaporation can be increased greatly without increasing the fraction which is degraded. If, therefore, the effect of temperature on the rate of evaporation is known, it is possible to define the conditions of time and temperature at which decomposition is minimum.

In practice, the kinetics of degradation and the relation of evaporation rate and temperature are usually not known. This is particularly true when the criteria by which the product is judged are color, taste, or smell. In addition, this

Fig. 1 The effect of time and temperature of degradation.

analysis neglects the temperature variation in the evaporating liquid and the degradation in boundary films where temperatures are higher. Therefore, experiments are often necessary to determine the suitability of an evaporation process.

In batch processes, the time of exposure to heat is well defined. This is also true of continuous processes in which the liquid to be evaporated is passed only once through the heater. In continuous processes, where the liquid is recirculated through the heater, the average residence time, a , is given by the ratio.

The volumetric discharge is only an indication of the damage that may be caused by prolonged heating. If perfect mixing occurs in the evaporator, the fraction, f , which is in the unit for time t or less, is given by Eq. 4.

$$f = 1 - e^{-t/a} \quad (4)$$

This relation shows that an evaporator, for example, with an average residence time of 1 h holds 13.5% of active principles for 2 h and about 2% for 4 h.

Evaporators

It is convenient to classify evaporators into natural circulation evaporators, forced-circulation evaporators, and film evaporators.

Natural circulation evaporators

Small-scale evaporators consist of a simple pan heated by a jacket or a coil, or both. Admission of the heating fluid to the jacket induces the liquid in the vessel to boil. Very small evaporators may be open, the vapor escaping to atmosphere or into a vented hood. Larger pan evaporators are closed, the vapor escaping through a pipe. Small

jacketed pans are efficient and easy to clean and may be fitted for the vacuum evaporation of thermolabile materials. Their size, however, is limited because the ratio of heating area to volume decreases as the capacity increases. Larger vessels must employ a heating coil which increases their evaporating capacity but it also makes cleaning more difficult.

Forced-circulation evaporators

On the smallest scale, forced-circulation evaporators are similar to the pan evaporators described previously, modified only by the inclusion of an agitator. Vigorous agitation increases the boiling film coefficient, the degree of which depends on the type and speed of the agitator. An agitator should be used for the evaporation of viscous materials to prevent degradation of material at the heated surfaces. Some large-scale continuous units are similar to the natural circulation evaporators already described.

Film evaporators

In the short tubes of the calandria, an intimate mixture of vapor and liquid is discharged at the top as shown in Fig. 2a. If the length of the tube is greatly increased, progressive phase separation occurs until a high velocity core of vapor is formed which propels an annular film of liquid along the tube. This phenomenon, which is one stage of flow when a liquid and a gas pass in the same direction along a tube, is employed in film evaporators. The turbulence of the film gives very high heat transfer coefficients, and the bubbles and vapor evolved are rapidly swept into the vapor stream. Although recirculation may be adopted, it is possible with the high evaporation is found in long tubes to sufficiently concentrate the liquid in a single pass. Because a very short residence time is obtained, very thermolabile materials may be concentrated at relatively high temperatures. Film evaporators are also

Fig. 2 (a) Evaporator with calandria; (b) climbing film evaporator.

suitable for materials which foam strongly. Various types have been developed, but all are essentially continuous in operation and their capacity starts from a few liters per hour upward.

The climbing film evaporator, which is the most common film evaporator, consists of tubes 15 to 30 feet (4.5–13.6 m) long and 1 to 2 in. (2.5–5 cm) in diameter mounted in a steam chest (Fig. 2b). The feed liquid enters the bottom of the tubes and flows upward for a short distance before boiling begins. The length of this section, which is characterized by low heat transfer coefficients, may be minimized by preheating the feed to its boiling point. The pattern of boiling and phase separation follows and a mixture of liquid and vapor emerges from the top of the tube to be separated by baffles or by a cyclone separator. Climbing film evaporators are not suitable for the evaporation of viscous liquids.

In the falling film evaporator, the liquid is fed to the top of a number of long heated tubes. Because the gravity assists the flow down the tube, this arrangement is better suited to the evaporation of moderately viscous liquids. The vapor evolved is usually carried downward and the mixture of liquid and vapor emerges from the bottom for separation. Even distribution of liquid must be secured during feeding. The tendency to channel in some tubes leads to drying in others.

The rising-falling film evaporator concentrates a liquid in a climbing film section and leads the emerging liquid and vapor into a second tube section which forms a falling film evaporator. Good distribution of liquid is claimed in the falling film section and this type is particularly suitable for liquids which greatly increase in viscosity during evaporation.

In mechanically aided film evaporators, a thin film of material is maintained on the heat transfer surface irrespective of the viscosity. This is usually achieved by means of a rotor, concentric with the tube, which carries blades that either scrape the tube or ride with low clearance in the film. Mechanical agitation permits the evaporation of highly viscous materials or those that have a low thermal conductivity. Because the temperature variations in the film are reduced and residence times are shortened, the vacuum evaporation of viscous thermolabile materials becomes possible.

Evaporation without boiling

During heating, some evaporation takes place at the surface of a batch of liquid before boiling begins. Similarly, liquids that are very viscous or excessively frothy may be concentrated without boiling. The diffusion of vapor from the surface is described by Eq. 5,

$$N_A = k_g RT(P_{Ai} - P_{Ag}) \quad (5)$$

where N_A is the number of moles evaporating from unit area in unit time, k_g is the mass transfer coefficient across the boundary layer, R is the gas constant, T is the absolute temperature, P_{Ai} is vapor pressure of the liquid, and P_{Ag} is the partial pressure of the vapor in the gas stream; k_g is proportional to the gas velocity.

Distillation

Distillation is a process in which a liquid mixture is separated into its component parts by vaporization. The vapor evolved from a boiling liquid mixture is normally richer in the more volatile components than the liquid with which it is in equilibrium. Distillation rests upon this fact. Although multicomponent mixtures are most common in distillation processes, an understanding of the operation can be based on the vapor pressure characteristics of two-component or binary mixtures.

Binary mixtures of immiscible liquids: steam distillation

If the components of a binary mixture are immiscible, the vapor pressure of the mixture is the sum of the vapor pressures of the two components, each exerted independently and not as a function of their relative concentrations in the liquid. This property is employed in steam distillation, a process particularly applicable to the separation of high boiling substances from nonvolatile impurities. The steam forms a cheap and inert carrier. The principles of the process also apply to other immiscible systems.

The composition of the distillate is calculated in the following way. For two components, A and B, the total vapor pressure, P , is the sum of the vapor pressures of the components, P_A and P_B . Since the partial pressure of a component in a gaseous mixture is proportional to its molar concentration, the composition of the vapor is given by Eq. 6,

$$\frac{n_A}{n_B} = \frac{P_A}{P_B} \quad (6)$$

where n_A and n_B are the number of moles of A and B in the vapor, respectively. If W_A and W_B are the weights of A and B in the vapor, Eq. 7 holds,

$$\frac{W_A}{M_A} = \frac{M_B}{W_B} = \frac{P_A}{P_B} \quad (7)$$

where M_A and M_B are the respective molecular weights. The distillate obtained from the vapor is $W_A + W_B$, and the percentage of A in the distillate is expressed by Eq. 8.

$$\frac{W_A}{M_A + W_B} \times 100 = \frac{P_A M_A}{P_A M_A + P_B W_B} \times 100 \quad (8)$$

The ratio of immiscible organic liquid to water in the distillate is increased if the former has a high molecular weight or a high vapor pressure. Steam distillation under vacuum may be employed when the thermal stability of the material prohibits temperatures of approximately 100°C.

The relation of vapor pressure and mixture composition: In a binary mixture of two completely miscible components, the vapor pressure is a function of the mixture composition as well as of the vapor pressures of the two pure components. If the liquids are ideal, the relation of vapor pressure and composition is given by Raoult's law. At a constant temperature, the partial vapor pressure of a constituent of an ideal mixture is proportional to its mole fraction in the liquid. Thus, for a mixture of A and B, the partial vapor pressure of A is given by Eq. 9,

$$P_A = P_A^0 \cdot x_A \quad (9)$$

where P_A^0 is the vapor pressure of pure A and x_A is its mole fraction. Similarly, the partial vapor pressure of B is expressed by Eq. 10.

$$P_B = P_B^0 \cdot x_B \quad (10)$$

The total pressure of the system, P , is simply $P_A + P_B$.

Very few liquid mixtures rigidly obey Raoult's law. Consequently, the vapor pressure data must be determined experimentally. Mixtures that deviate positively from this law give a total vapor pressure curve which lies above the theoretical straight line. Negative deviations fall below the line. In extreme cases, deviations are so large that a range of mixtures exhibits a higher or lower vapor pressure than either of the pure components.

Returning to ideal systems, the partial pressure of a component in the vapor is proportional to its mole fraction, as shown in Eq. 11 for component A,

$$P_A = y_A P \quad (11)$$

where P_A is the partial pressure of A in the vapor and y_A is its mole fraction. Because, $P_A = P_A^0 x_A$, Eqs. 12 and 13 can be written as:

$$y_A = \frac{x_A P_A^0}{P} \quad (12)$$

similarly,

$$y_B = \frac{x_B P_B^0}{P} \quad (13)$$

If A is the more volatile component, P_A^0 is greater than P_B^0 . Therefore y_A is greater than x_A , that is, the vapor is richer

in the more volatile component than the liquid with which it is in equilibrium.

Systems that form minimum boiling mixtures are common. Ethyl alcohol and water provide an example, the azeotrope containing 4.5% by weight of water. The boiling point at atmospheric pressure is 78.15°C that is 0.25°C lower than the boiling point of pure alcohol. Maximum boiling mixtures are less common. The most familiar example is hydrochloric acid which forms an azeotrope boiling at 108.6°C containing 20.2% by weight of hydrochloric acid. Mixtures that form azeotropes cannot be separated into the pure components by normal distillation methods. However, separation into the azeotrope and one pure component is possible.

Simple or differential distillation

In simple or differential distillation, the vapor evolved from the boiling mixture is immediately removed and condensed. Unless the boiling points of the two pure components differ widely, a reasonable degree of separation is not possible. This method may be used to remove low boiling solvents from aqueous solutions.

Rectification or fractionation

In simple distillation, vapor enrichment is small. In fractionation, a term synonymous with rectification, the vapor leaving the boiling liquid is led up a column to meet a liquid stream or reflux which originates higher in the column as part of the condensate. In a series of partial condensations and vaporizations, the rising vapor becomes richer in the more volatile component at the expense of the falling liquid and high degrees of separation become possible. The columns, called fractionating columns, are of two basic types: packed columns and plate columns.

Packed columns: These are used for laboratory and small-scale industrial distillation and are usually operated as a batch process. The column consists of a vertical, hollow, cylindrical shell containing a packing designed to offer a large interfacial contact area between liquid and vapor. The form of the packing varies but Raschig rings, which consist of small metallic or ceramic cylinders, are the most commonly used. In general, packed columns operate under widely varying conditions without serious loss of efficiency.

Plate columns: A plate column consists of a series of plates or trays on which the liquid is retained for some period during its movement down the column. The rising vapor is bubbled through this liquid, providing intimate contact between the phases. Liquid in reflux moves downward between plates and is usually carried by a downcomer. Contact between the vapor and liquid takes place in stages.

Plate columns operate efficiently over a limited range of conditions. They are mainly used in large-scale continuous installations in which the conditions of distillation can be closely maintained.

Molecular distillation

Molecular distillation is carried out without boiling at very low pressures of the order 0.001 mm Hg (0.133 Pa). At these pressures, collision of molecules in the evolving vapor and reflection back to the liquid surface is greatly decreased and the mean free path of the molecules is of the same order as the distance between the evaporating surface and a condenser placed a short distance away. It then becomes possible to distil liquids of very high boiling point although the degree of separation cannot exceed one theoretical plate. The process therefore is used primarily to concentrate nonvolatile components in a high boiling medium. The vitamins in cod liver oil can be concentrated this way. For the separation of liquids of comparable volatility, several separate distillation stages are necessary.

Because agitation due to boiling is absent, an alternative method of maintaining the more volatile component at the evaporating surface must be adopted. In the industrial molecular still shown in Fig. 3, the feed is introduced at the bottom of a heated conical rotor and flows upward as a thin liquid layer under the action of centrifugal force. The residue is caught in a gutter at the top. The vapor is condensed on a concentric, water-cooled condenser a short distance away and discharged.

AIR CONDITIONING AND HUMIDIFICATION

General principles of the supply of air in pharmaceutical processes are similar to conventional air conditioning. The control of its quality, however, may be more stringent. In areas where sterile materials are made and handled, for example, the cleaning process must remove bacteria. In other situations, it may be necessary to remove water vapor. The flow of powders is a sensitive function of moisture content, and the equilibrium moisture content of a material is determined by the humidity. Some tableting processes break down if the humidity is too high. In such processes, the scale of the air conditioning varies. It may be necessary to supply a whole room with air of a certain quality. Alternatively, conditioning may be restricted to a small area surrounding a particular piece of equipment.

Vapor and Gas Mixtures

The study of the properties of the air–water vapor mixture is called psychrometry, and data are presented in various forms of psychrometric charts presenting various data. In Fig. 4, humidity is plotted as ordinate and temperatures as abscissa. Percentage of relative humidity is plotted as curves running across the chart. The use of this simplified chart is demonstrated later.

Fig. 3 Large-scale molecular still. (From Ref. 3)

Fig. 4 A psychrometric chart.

Hygrometry, the Measurement of Humidity

The accurate determination of the humidity of air is carried out gravimetrically. The water vapor present in a known volume of air is chemically absorbed with a suitable reagent and weighed. In less laborious methods, the humidity is derived from the dew point or the wet-bulb depression of a water–vapor mixture.

The dew point is the temperature at which a vapor condenses when cooled at constant pressure. If air of the condition denoted by point A in Fig. 4 is cooled, the relative humidity increases until the mixture is fully saturated. This condition is given by point B; the temperature coordinator is the dew point, which can be measured rapidly by evaporating ether in a silvered bulb. The temperature at which dew deposits from the surrounding air is noted and the humidity is read directly from a psychrometric chart.

The derivation of the humidity from the wet-bulb depression requires a preliminary study of the transfer of mass and heat at a boundary between air and water. The difference between the air temperature and the wet-bulb temperature is the wet-bulb depression. If these temperatures are denoted by T_a and T_{wb} , the rate of heat transfer, Q , is given by Eq. 14,

$$Q = hA(T_a - T_{wb}) \quad (14)$$

$$Q = \rho k_g A(H_i - H_a) \quad (15)$$

Equating Eqs. 14 and 15 gives Eq. 16.

$$H_i - H_a = \frac{h}{\rho k_g \lambda} (T_a - T_{wb}) \quad (16)$$

Both the heat and mass transfer coefficients are functions of air velocity. However, at air speeds greater than about 15 ft/s (4.5 m/s), the ratio $h:k_g$ is approximately constant. The wet-bulb depression is directly proportional to the difference between the humidity at the surface and the humidity in the bulk of the air. In the wet- and dry-bulb hygrometer, the wet-bulb depression is measured by two thermometers, one of which is fitted with a fabric sleeve wetted with water. These thermometers are mounted side by side and shielded from radiation, an effect neglected in the derivation above. Air is drawn over the thermometers by means of a small fan. The derivation of the humidity from the wet-bulb depression and a psychrometric chart are discussed later.

Many wet- and dry-bulb hygrometers operate without any form of induced air velocity at the wet bulb. This may be explained by examining another air–water system. If a limited quantity of air and water is allowed to equilibrate under conditions in which heat is neither gained nor lost by the system, the air becomes saturated and the latent heat required for evaporation is drawn from both fluids which cool to the same temperature. This temperature is the adiabatic saturation temperature, T_∞ . It is a peculiarity of the air–water system that the adiabatic saturation temperature and the wet-bulb temperature are the same. If water at this temperature is recycled in a system through which air is passing, the incoming air is cooled till it reaches the adiabatic saturation temperature at which point it is saturated. The temperature of the water, on the other hand, remains constant and all the latent heat required for evaporation is drawn from the sensible heat of the air. Equilibrium is expressed by Eq. 17,

$$(T_a - T_\infty)S = (H_\infty - H_a)\lambda \quad (17)$$

where T_a is the temperature of the incoming air and S is its specific heat, H_a and H_∞ are the humidities of the incoming air and the saturated air, and λ is the latent heat of evaporation for water.

When both wet- and dry-bulb temperatures have been found, the humidity is read from the psychrometric chart in the following way. The point on the saturation curve corresponding to the wet-bulb temperature is found first. An adiabatic cooling line is then interpolated and followed until the coordinate corresponding to the dry-bulb temperature is reached. The humidity is read from the other axis.

Humidification and Dehumidification

Most commonly, air is humidified by passage through a spray of water. Small quantities of air are easily dehumidified by adsorbing the water vapor with alumina or silica gel arranged in columns. These are mounted in pairs so that one can be regenerated while the other is in use. Alternatively, the air can be cooled below the dew point. Excess water vapor condenses and the cold saturated air is reheated.

CRYSTALLIZATION

The term crystallization describes the production of a solid, single-component, crystalline phase from a multi-component fluid phase. The importance of crystallization lies primarily in the purification achieved during the process and in the physical properties of the product. A crystalline powder is easily handled, stable, and often possesses good flow properties and an attractive appearance.

Crystallization from a vapor, which occurs naturally, e.g., in the formation of hoar frost, is employed in sublimation processes and for the condensation of water vapor during freeze-drying.

Crystallization in Melts

A melt may be defined as the liquid form of a single material or the homogeneous liquid form of two or more materials which solidify on cooling. Crystallization in such a system passes through the following stages: supercooling, nuclei formation, and crystal growth.

If a single-component liquid is cooled, some degree, often high, of supercooling must be established before crystal nuclei form and growth begins. A metastable liquid region exists below the melting point which only can be entered by cooling. In this metastable, supercooled region, the absence of nucleation precludes the formation and growth of crystals. If, however, a crystal seed is added, growth occurs. The deliberate seeding of a metastable system is commonly employed in industrial crystallization. With further cooling, spontaneous nucleation usually takes place and the released heat of crystallization raises the temperature of the melt to its true melting point.

Nucleation

In certain single-component systems, such as piperine, nucleation and crystal growth are independent and can be

separately studied. The rate of nucleation as a function of supercooling is studied by maintaining the melt for a certain time at the given temperature and then quickly raising the temperature to the metastable region where further nucleation is negligible but the already formed nuclei can grow.

Spontaneous nucleation occurs when sufficient molecules of low kinetic energy come together in such a way that the attraction between them is sufficient to overcome their momentum.

Crystal Growth

If nucleation and crystal growth are independent, the latter can be studied by seeding a melt with small crystals under conditions of little or no natural nucleation. The rate of growth can then be measured. The form of the crystal growth curve is again explained by the kinetics of the molecules. At temperatures just below the melting point, molecules have too much energy to remain in the crystal lattice. As the temperature falls, more molecules are retained and the growth rate increases. Ultimately, however, diffusion to and orientation at the crystal surface is depressed.

For crystal growth in a single component melt, the molecules at the crystal surface must reach the correct position at the lattice and become suitably orientated, losing kinetic energy. These energy changes appear as heat of crystallization, which must be transferred from the surface to the bulk of the melt. The rate of crystal growth is influenced by the rate of heat transfer and the changes taking place at the surface. Agitation of the system increases heat transfer by reducing the thermal resistance of the liquid layers adjacent to the crystal until the changes at the crystal face become the controlling effect.

In multicomponent melts and solutions, deposition of material at the crystal face depletes the adjacent liquid layers and a concentration gradient is set up with saturation at the face and supersaturation in the liquid. Diffusion of molecules to the crystal face is discussed in the next section.

Crystallization from Solutions

During crystal growth, a high degree of supersaturation promotes a high growth rate. A reaction at the surface, in which, solute molecules become correctly orientated in the crystal lattice, provides a second resistance to the growth of the crystal. Simultaneously, the heat of crystallization must be conducted away.

For given conditions of temperature and saturation, agitation modifies the rate of crystal growth. Initially,

agitation quickly increases the growth rate by decreasing the thickness of the boundary layer and the diffusional resistance. However, as agitation is intensified, a limiting value is reached which is determined by the kinetics of the surface reaction.

As with melts, soluble impurities may increase or reduce nucleation rate. Insoluble materials may act as nuclei and promote crystallization. Impurities may also affect crystal form and, in some cases, are deliberately added to secure a product with good appearance, absence of caking, or suitable flow properties.

Crystallizers

Although other methods may be adopted, crystallizers can be classified conveniently in the same way, a solution is supersaturated. This leads to the self-explanatory terms, cooling crystallizer and evaporate crystallizer. In vacuum crystallizers, evaporation and cooling both take place.

FILTRATION

Filtration may be defined as the removal of solids suspended in a liquid or gas by passage through a pervious medium on which the solids are retained. The pervious medium or septum is normally supported on a base and these, together with a suitable housing providing free access of fluid to and from the septum, comprise the filter.

Methods

Clarification

Clarification of parenteral solutions eliminates unwanted solids normally present in very small concentrations. This may be carried out with the help of thick media, which allow the penetration and arrest of particles by entrapment, impingement, and electrostatic effects. This procedure leads to the concept of depth filtration in which particles, perhaps a hundred times smaller than the dimensions of the passages through the medium, are removed. Such filters are not absolute and must be designed with sufficient depth so that the probability of the smallest particle under consideration passing right through the filter is extremely small.

Depth filtration fundamentally differs from the use of media in which pore size determines the size of particle retained. Such filters may be said to be "absolute" at a particle diameter closely related to the size of the pore, so that there is a relatively sharp division between particles which pass the filter and those that are retained. An analogy

with sieving may be drawn for this mechanism. The life of such filters depends on the number of pores available for the passage of fluid. Once a particle is trapped at the entrance to the pore, the contribution of the latter to the overall flow of liquid is very much reduced. Coarse straining with a wire mesh and membrane filter employ this mechanism. Sterilization of liquids by filtration could be regarded as an extreme application of clarification in which the complete removal of particles as small as 0.3 μm must be ensured.

Cake filtration

The most common industrial application is the filtration of slurries containing a relatively large amount of suspended solids, usually 3 to 20%. The septum acts only as a support in this operation, the actual filtration being carried out by the solids deposited as a cake. In such cases, solids may completely penetrate the septum until the deposition of an effective cake occurs. Until this time, cloudy filtrate may be recycled. The physical properties of the cake largely determine the method employed. Washing and partial drying or dewatering are often integral parts of the process. Effective discharge of the cake completes the process. The solids, the filtrate, or both may be wanted.

The Theories of Filtration

Filtration theory has two important aspects. The first describes the flow of fluids through porous media and is applicable to both clarification and cake filtration. The second, which is of primary importance only in clarification, is the retention of particles on a depth filter.

Flow of fluids through porous media

The concept of a channel with a hydraulic diameter equivalent to the complex interstitial network which exists in a powder bed leads to Eq. 18,

$$Q = \frac{KA \Delta P}{\eta L} \quad (18)$$

where Q is the volumetric flow rate, A is the area of the bed and L its thickness, ΔP is the pressure difference, and η is the viscosity of the fluid. The permeability coefficient, K , is given by

$$\frac{\varepsilon^3}{5(1 - \varepsilon)^2 S_0^2}$$

where ε is the porosity of the bed and S_0 its specific surface area (cm^2/cm^3).

In clarification, high permeability and filtration rate oppose good particle retention. In the formation of clarify-

ing media from sintered or loose articles, accurate control of particle size, specific surface and porosity is possible, and, a medium can be designed which offers the best compromise between permeability and particle retention. The analysis of permeability given above can be accurately applied to these systems. Because of extremes of shape, this is not so with the fibrous media used for clarification. Here it is possible to develop a material of high permeability and high retentive capacity. Such a material is, however, intrinsically weak and must be adequately supported.

A mathematical account of the theories of clarification with depth filters is found in the work of Ives (4, 5) and Maroudas and Eisenklam (6).

Filters

The method by which the filtrate is driven through the filter medium and cake, if present may be used to classify filters into:

- Gravity filters
- Vacuum filters
- Pressure filters

Each group may be further subdivided into filters employed in continuous or batch processes although, due to technical difficulties, continuous pressure filters are uncommon and expensive. Centrifugation is another means of removing filtrate. Extensive surveys can be found in the literature (7, 8).

Many small-scale filters simply consist of a fixed, rigid medium, robust enough to withstand limited pressures, mounted in a suitable housing. These filters, which are also vacuum operated, are used to clarify by depth filtration. Media are composed of sintered metals, ceramics, plastics, or glass. Filters prepared from closely graded and sintered chemical powders are suitable for the sterilization of solutions by filtration on a manufacturing scale.

Filter Media

In cake filtration, the medium must oppose excessive penetration and promote the formation of a junction with the cake, to high permeability. The medium should also give free discharge of cake after washing and dewatering.

Rigid media

Rigid media may be loose or fixed. The former is exemplified by the deposition of a filter aid on a suitable support. Filtration characteristics are governed mainly by particle size, size distribution, and shape in a manner described earlier. These factors may be varied for different filtering requirements.

Fixed media vary from perforated metals used for coarse straining for the removal of very fine particles with a sintered aggregate of metal, ceramic, plastic, or glass powder. The size, size distribution, and shape of the powder particles together with the sintering conditions control the size and distribution of the pores in the final product. The permeability may be expressed in terms of the coefficient given in Eq. 18. Alternatively, the medium may be characterized by air permeability. The maximum pore size, which is important in the selection of filters for sterilization, may be determined by measuring the pressure difference required to blow a bubble of air through the medium while it supports a column of liquid with a known surface tension.

Flexible media

Flexible media may be woven or unwoven. Filter media, woven from cotton, wool, synthetic and regenerated fibers, and glass and metal fibers, are used as septa in cake filtration. Cotton is the most widely used natural fiber, nylon is predominant among synthetic fibers. Terylene is a useful medium for acid filtration. Penetration and cake discharge are influenced by twisting and plying of fibers and by the adoption of various weaves such as duck and twill. The choice of a particular cloth often depends on the chemical nature of the slurry.

Nonwoven media in the form of felts and compressed cellulose pulps, are used for clarification by depth filtration. Unless carefully prepared, they have the disadvantage of losing fibrous material from the downstream side of the filter. The application of sheet media has been discussed earlier. High wet strength is conferred on paper sheets by resin impregnation. An alternative technique employs asbestos fibers supported in a cellulose framework.

Mechanism of air filtration

A theoretical foundation for the filtration of air by passage through fibrous media was laid in the early 1930s by studies of the flow of suspended particles around various obstacles. In studies of the filtration of smokes (9, 10) it has been shown that the following factors operate simultaneously in the arrest of a particle during its passage through a filter, although their relative importance varies with the type of filter and the conditions under which it is operated.

- Diffusion effects due to Brownian movement
- Electrostatic attraction between particles and fibers
- Direct interception of a particle by a fiber
- Interception as a result of inertial effects acting on a particle and causing it to collide with a fiber
- Settling and gravitational effects

Air filters operate under conditions of streamline flow as indicated by the streamlines drawn around a cylindrical fiber. It was assumed that capture of a particle takes place if any contact is made during its movement around the fiber. Once captured, the particle is not re-entrained in the air stream and deposited deeper in the bed. Support for this assumption has been found by using an atomized suspension of *Staphylococcus albus* and spores of *Bacillus subtilis* (11). Nevertheless, some fiber filters are treated with viscous oils, presumably to make capture more positive and to reduce re-entrainment.

Deviation of particles from streamlines can occur in a number of ways (10, 12). The chance of capture increases if Brownian movement causes appreciable migration across streamlines, an effect only important for small particles (less than 0.5 μm) and low air speeds, when the time span spent in the vicinity of a fiber is relatively long. These conditions also apply to capture which is the result of electrostatic attraction.

Sampling efficiency has been demonstrated for bacterial aerosols (13) in a study of the efficiency with which a glass fiber mat collected *B. subtilis* spores atomized as particles just over a micrometer in radius. A theoretical approach to the removal of industrial dusts has been developed (14–16).

Design, operation, and testing of air filters

Granular beds, fibrous media, and “absolute filters” prepared from cellulose and asbestos are used for high-efficiency air filtration. With fibrous and granular filters, the fractional reduction in particle content is assumed to be the same through successive incremental thicknesses of the filter, expressed by Eq. 19,

$$\frac{dC}{dx} = -kC \quad (19)$$

where C represents the number of particles entering a section of thickness dx . The constant, k , is a measure of the filter's ability to retain a particle. It is a complex function of fiber diameter, interfiber distance, and the operational air velocity. Integration between inlet and outlet conditions gives Eq. 20.

$$\log \frac{C_{\text{out}}}{C_{\text{in}}} = -kC \quad (20)$$

The use of this log penetration effect in filter design has been described elsewhere (17). If a certain filter thickness is capable of retaining 90% of the entering particles and 10^6 particles enter, 10^5 penetrate. If six thicknesses are used, Eq. 21 predicts that only one particle penetrates. The

log-penetration effect has been confirmed for fibrous filters (13) and granular beds (18).

Centrifugal Operations

An object moving in a circular path is subjected to an outward centrifugal force which balances the centripetal force moving the object toward the center of rotation. This principle is used in the mechanical separations called centrifugal filtration and centrifugal sedimentation. In the former, a material is placed in a rotating perforated basket which is lined by a filter cloth used to separate a solid, which is retained at the cloth, from a liquid. It is essentially a filtration process in which the driving force is of centrifugal origin. This does not depend upon a difference in the density of the two phases.

In centrifugal sedimentation, the separation is due to the difference in the density of two or more phases. This is the more important process, where both solid–liquid mixtures and liquid–liquid mixtures can be completely separated. If, however, the separation is incomplete, there is a gradient in the size of the dispersed phase within the centrifuge due to the faster radial velocity of the larger particles. Operated in this way, the centrifuge becomes a classifier.

Centrifugal sedimentation

The motion of a particle in a liquid is described by Stokes' equation. If its diameter is d , the rate u at which it settles by gravity in a liquid of viscosity η and density ρ is given by Eq. 21

$$u = \frac{1}{18} d^2 \frac{\rho_s - \rho}{\eta} g \quad (21)$$

where g is the acceleration due to gravity, and ρ_s is the density of the particle. In the centrifuge, the gravitational force causing separation is replaced by a centrifugal force. If the particle has a mass m and moves at an angular velocity ω in a circle of radius r , the centrifugal force is $\omega^2 r(m - m_1)$, where m_1 is the mass of the displaced liquid. The expression

$$\frac{\omega^2 r}{g}$$

is, therefore, the ratio of the centrifugal and gravitational forces in the example described previously. Its value can exceed 10,000. The separation is quicker, more complete, and effective in systems containing very fine particles which do not settle by gravity because of Brownian movement.

Expressing the mass of the particle in terms of its volume and effective density, the centrifugal force can be written as in Eq. 22.

$$\frac{\pi}{6} d^2 (\rho_s - \rho) \omega^2 r \quad (22)$$

In streamline conditions, the opposing viscous force is $3\pi \eta u$, where u is the terminal velocity of the particle. Equating these expressions gives Eq. 23.

$$u = \frac{1}{18} d^2 \frac{(\rho_s - \rho)}{\eta} \omega^2 r \quad (23)$$

The rate of sedimentation is proportional to the radius of the basket and the square of the speed at which it rotates. Centrifugal sedimentors can be divided into a number of types. For operations at very high speeds, the centrifuge bowl is tubular with a length/diameter ratio from 4 to 8. The solids are periodically discharged by scraping the walls of the centrifuge tube. Uses include the cleaning of fats and waxes, the fractionation of blood, and the recovery of viruses.

DRYING

Drying may be defined as the vaporization and removal of water or other liquid from a solution, suspension, or other solid-liquid mixture to form a dry solid. The change of phase from liquid to vapor distinguishes drying from the mechanical methods of separating solids from liquids such as filtration. The latter often precede drying because they offer a cheaper method for removing a large part of the liquid, where applicable.

Adjustment and control of moisture levels by drying, is important in the manufacture and development of pharmaceutical products. Apart from the obvious requirement of dry solids for many operations, drying may be carried out in order to:

- Improve handling characteristics, as in bulk powder filling and other operations involving powder flow, and
- Stabilize moisture-sensitive materials, such as aspirin and ascorbic acid.

Theory

The following terms are employed in discussing drying: humidity and humidity of saturated air, relative humidity, wet-bulb temperature, and adiabatic cooling line. Other terms may be defined as:

- **Moisture Content.** It is usually expressed as weight per unit weight of dry solids.
- **Equilibrium Moisture Content.** If a material is exposed to air at a given temperature and humidity, it will gain or lose moisture until equilibrium is reached. The moisture present at this point is defined as the equilibrium moisture content for the given exposure conditions. At a given temperature, it will vary with the partial pressure of the water vapor in the surrounding atmosphere.

Equilibrium moisture content curves vary greatly with the type of material examined. Insoluble, nonporous materials, such as talc or zinc oxide, have equilibrium moisture contents of almost zero over a wide humidity range. A moisture content between 10 and 15% may be expected for cotton fabrics under normal atmospheric conditions. Drying below the equilibrium moisture content for room conditions may be deliberately undertaken, particularly if the material is unstable in the presence of moisture; subsequent storage becomes important.

The effects of storage after drying also may be assessed from the equilibrium moisture content curves. Storage conditions are not critical for the lactose granulation (19, 20). If the antacid formulation is stored at a relative humidity of only 65% it would, given sufficient time, absorb moisture until the content was 91%. This could be associated with poor flow characteristics and its attendant difficulties during compression.

Evaporation of Water into an Air Stream

The evaporation of moisture into a warm air stream, with the latter providing the latent heat of evaporation, is a common drying mechanism although it is not easily adapted to the recovery of the liquid. In the evaporation from a liquid surface which, with the passage of air, falls to the wet bulb temperature corresponding to the temperature and humidity of the air, the rate at which water vapor is transferred from the saturated layer at the surface to the drying stream is described by Eq. 15,

$$N = \frac{k_g}{RT} (P_{wi} - P_{wa})$$

where P_{wi} is the partial pressure of the water vapor at the surface, P_{wa} is the partial pressure of water vapor in the air, k_g is a mass transfer coefficient, and N the number of moles vapor transferred from unit area in unit time. Rewriting this in terms of the total mass, W , transferred in unit time from the entire drying surface A gives Eq. 6,

$$W = \frac{M_w A}{RT} k_g (P_{wi} - P_{wa})$$

where M_w is the molecular weight of water vapor, R is the gas constant, and T the absolute temperature. The mass transfer coefficient, k_g , is a function of the temperature, the air velocity, and the angle of air incidence. A high velocity or angle of incidence diminishes the thickness of the stationary air layer in contact with the liquid surface and therefore lowers the diffusional resistance.

The rate of evaporation may also be expressed in terms of the heat transferred across the laminar film from the drying gases to the surface, as shown in Eq. 9,

$$Q = hA(T_a - T_s)$$

where Q is the rate of heat transfer, A is the area of the surface, T_a and T_s , are the temperatures of the drying air and the surface, respectively, and h is the heat transfer coefficient. The last is also a function of air velocity and the angle of impingement. If the latent heat of evaporation is λ , this affords a mass transfer rate, W , which is given by Eq. 24.

$$W = \frac{hA}{\lambda}(T_a - T_s) \quad (24)$$

When these conditions pertain to drying, the surface temperature, T_s , which is the wet bulb temperature, is normally much lower than the temperature of the drying gases. This is of great importance in the drying of thermolabile materials. If solids are present in the surface, the rate of evaporation is modified, the overall effect depending on the structure of the solids and the moisture content.

Static Beds of Nonporous Solids

The drying of wet granular beds containing nonporous particles, which are insoluble in the wetting liquid, has been extensively studied. The operation is presented as the relation of moisture content and time of drying in Fig. 5a.

Fig. 5 (a) Relation of moisture content and time of drying; (b) rate of drying and moisture content.

It should be noted that the equilibrium moisture content is approached slowly. A protracted period may be required for the removal of water just above the equilibrium value. This is not justified if a small amount of water can be tolerated in further procession establishing realistic drying requirements.

The data have been converted to a curve relating the rate of drying to moisture content in Fig. 5b. The initial heating period during which equilibrium is established is short and has been omitted from both figures. Assuming that sufficient moisture is initially present, the drying-rate curve exhibits three sections limited by the points A, B, C, and D. In section A-B, called the constant-rate period, moisture is evaporating from a saturated surface at a rate governed by the stationary air film in contact with it. An analogy with evaporation from a plain water surface can therefore be drawn and Equations (11) and (13) apply. The rate of drying during this period depends upon the air temperature, humidity, and speed, which in turn determine the temperature of the saturated surface. Assuming that these are constant, all variables in the drying equations given earlier are fixed, and a constant rate of drying is established which is largely independent of the material being dried. The drying rate is somewhat lower than for a free-water surface and to some extent depends on the particle size of the solids. During the constant-rate period, liquid must be transported to the surface at a rate sufficiently high to maintain saturation. The mechanism of transport is discussed later.

At the end of the constant-rate period B, a break in the drying curve occurs. This point is called the critical moisture content, and a linear fall in the drying rate occurs with further drying. Because section, B-C, is called the first falling-rate period. At and below the critical moisture content, the movement of moisture from the interior is no longer sufficient to saturate the surface. As drying proceeds, moisture reaches the surface at a decreasing rate and the mechanism which controls its transfer influences the rate of drying. Because the surface is no longer saturated, it tends to rise above the wet bulb temperature.

For any material, the critical moisture content decreases as the particle size decreases. Eventually, moisture ceases to reach the surface which becomes dry. The plane of evaporation recedes into the solid, the vapor reaching the surface by diffusion through the pores of the bed. This section is called the second falling-rate period and is controlled by vapor diffusion, a factor which is largely independent of the conditions outside the bed but markedly affected by the particle size due to its influence on the dimensions of pores and channels. During this period, the surface temperature approaches the temperature of the drying air.

Considerable migration of liquid occurs during the constant-rate and first falling-rate periods. Associated with the liquid is any soluble constituent which forms a concentrating solution in the surface layers as drying proceeds. Deposition of these materials takes place when the surface dries. Considerable segregation of soluble elements in the cake can occur, therefore, during drying. These effects have been fully investigated (21).

The Internal Mechanism of Drying

Capillary forces offer a coherent explanation for the drying periods of many materials. If a tapered capillary is filled with water and exposed to a current of air, the meniscus at the smaller end remains stationary while the tube empties from the wider end. A similar situation exists in a wet particulate bed and the phenomenon is explained by the concept of suction potential. A negative pressure exists below the meniscus of a curved liquid surface which is proportional to the surface tension, λ , and inversely proportional to the radius of curvature, r . (The meniscus is assumed to be a part of a hemisphere.) This negative pressure or suction potential may be expressed as the height of liquid, expressed by Eq. 25,

$$h = \frac{2\lambda}{\rho g r} \quad (25)$$

where ρ is the density of the liquid.

The suction potential, h_x , acting at a depth x below the meniscus is given by Eq. 26.

$$h_x = h - x \quad (26)$$

The particles of the bed enclose spaces called pores connected by passages, the narrowest part of which is called the waist. The dimensions of the latter are determined by the size of the surrounding particles and the manner in which they are packed. In a randomly packed bed, pores and waists of varying sizes are found. Thus, the radius of a capillary running through the bed varies continuously. The depletion of water in this network is controlled by the waists because the radii of curvature are smaller and the suction potentials are greater than for the pores. The application of this mechanism has been described fully elsewhere (22, 23).

Through Air-Circulation Drying

If the particles are in a suitable granular form, it is often possible to pass the air stream downward through the bed of solids. Drying follows the pattern described previously, except that each particle or agglomerate behaves as a

drying bed. The surface area exposed to the drying gases is greatly increased, and the drying rates are 10 to 20 times higher than those encountered when air is passed over a free surface.

Methods Involving Movement of the Solid

As an extension of drying by passing the air stream through a static bed of solids, it is possible to project air upward through the bed at a velocity high enough to fluidize the particles. Alternatively, the material may be mechanically subdivided and introduced into the drying stream. Both methods give high drying rates due to high interfacial contact between the drying surfaces and the air stream. Fluidized bed driers and spray driers, respectively, are based on these principles.

Solids Moving Over a Hot Surface

Conditions in which the solids move over a heated surface are employed in tumbling and agitated driers. Drying rates are higher than those obtained in static beds because fresh solids are continually exposed to the hot surface. The heat treatment received by the solid is more uniform.

Batch Driers

Hot air ovens

Ovens operating by passing hot air over the surface of a wet solid which is spread over trays arranged in racks, provide the simplest and cheapest drier. In small installations, the air is passed over electrically heated elements and once through the oven. Larger units may employ steam-heated, finned tubes, and thermal efficiency is improved by recirculating the air. This is controlled by manually set dampers, and a common operating position gives 90% recirculation and 10% bleed-off. The heater bank is placed in such a position that the solids do not receive radiant heat and incoming air may be filtered.

The chief advantage of the hot air oven, apart from its low initial cost, is its versatility. With the exception of dusty solids, materials of almost any physical form may be dried. Thermostatically controlled air temperatures between 40 and 120°C permit heat-sensitive materials to be dried. For small batches this may be the equipment of choice. However, the following characteristics have led to development of other small driers:

- A large floor space is required for the oven and tray loading facilities.

- Labor costs for loading and unloading the oven are high.
- Long drying times, usually of the order of 24 h, are necessary.
- Solvents can be recovered from the air only with difficulty.
- Unless carefully designed, nonuniform distribution of air over the trays results in variations in temperature and drying times within the oven. Variations of $\pm 7^{\circ}\text{C}$ in temperature have been found from location to location during the drying of tablet granules (19). Poor air circulation may permit local saturation and the cessation of drying.

An extensive analysis of tray drying and the effect of operational variables has been given by Shepherd et al. (24).

If the material is of suitable granular form, drying times may be reduced to 1 h or less by passing the air downward through the material laid on mesh trays. The oven in this form is called a batch through-circulation drier.

Vacuum tray driers

Vacuum tray driers offer an alternative method for drying small quantities of material. When scaled up, construction becomes massive to withstand the applied vacuum and cost is further increased by the associated vacuum equipment. Vacuum tray driers are, therefore, only used when a definite advantage over the hot air oven is secured, such as low temperature drying of thermolabile materials or the recovery of solvents from the bed. The exclusion of oxygen may also be advantageous or necessary in some operations.

Heat is usually supplied by passing steam or hot water through hollow shelves. Radiation from the shelf above may cause a significant increase in temperature at the surface of the material if high drying temperatures are used. Drying times are long, usually of the order of 12 to 48 h.

Tumbling driers

The limitations of ovens, particularly with respect to the long drying times, has, where possible, promoted the design and application of other batch driers. The simplest of these is the tumbler drier. Its most common shape is the double cone (19). Operating under vacuum, it provides controlled low temperature drying, the possibility of solvent recovery, and increased drying rates. Heat is supplied to the tumbling charge by contact with the heated shell and heat transfer through the vapor.

A normal charge would be about 60% of the total volume and, for driers 2–7 ft (0.6–2 m) in diameter, drying times of 2–12 h may be expected. In studying the

application of tumbler driers to drying tablet granules, periods of 2–3.5 h were sufficient instead of 18 h required by hot air ovens (25). The mixing and granulating capacity of the tumbling action has suggested that these operations could precede drying in the same apparatus.

Fluid-bed driers

The term “fluidization” is applied to processes in which a loose, porous bed of solids is converted to a fluid system, having the properties of surface leveling, flow, and pressure-depth relationships, by passing the fluid up through the bed.

Fluidized-bed techniques, employing air as the fluidizing medium, have been successfully applied to the drying of solids of the suitable physical form. The high interfacial contact between drying air and solids gives drying rates 10 to 20 times higher than those obtained during tray drying.

Fluidized-bed driers are particularly suitable for granulated materials and are being increasingly used for tablet granulations, providing that product changeover is not too frequent. Machines vary in size, handling up to 250 kg. Drying times, maximum, minimum, and optimum air velocities, air temperature, and the tendency to cake and channel are established experimentally as those cannot be predicted accurately at present.

Agitated batch driers

Agitated batch driers consist of a jacketed cylindrical vessel with agitator blades designed to scrape the bottom and walls. They may operate at atmospheric pressure or under vacuum. Pasty materials that could not be handled in tumbling or fluidized-bed driers, may be successfully dried at rates higher than can be achieved in an oven.

Freeze drying

Freeze drying is an extreme form of vacuum drying in which the solid is frozen and drying takes place by subliming the solid phase (26–30) at low temperatures and pressures. Establishing and maintaining these conditions, together with the low drying rates obtained, constitutes the most expensive method of drying which is only used on a large scale when other methods are inadequate.

Freeze drying is extensively used when rapid decomposition occurs during normal drying. Another application concerns substances that can be dried at high temperatures but are thereby changed in some way.

Freeze drying is theoretically a simple technique. Pure ice exhibits an equilibrium vapor pressure of 4.6 mm Hg (611 Pa) at 0°C and 0.1 mm Hg (13.3 Pa) at -40°C . The vapor pressure of ice containing dissolved substances is, of course, lower. If, however, the pressure above the

frozen solution is less than its equilibrium vapor pressure, the ice sublimes, eventually leaving the solute as a sponge-like residue equal in apparent volume to the original solid.

Continuous Driers

Although many types of continuous driers are available, the scale of the operation for which they are designed is rarely appropriate to pharmaceutical manufacture. As with most continuous operations, the cost is disproportionately high for small units. Spray and drum driers provide an exception, because residence times in the driers are short and thermal degradation is minimized. Under some conditions, freeze drying may be the only practicable alternative.

Spray driers

The solution or suspension to be dried is sprayed into a hot air stream and circulated through a chamber. The dried product may be carried out to cyclone or bag separators or may fall to the bottom of the drying chamber and be expelled through a valve. The chambers are normally cylindrical with a conical bottom although proportions vary widely. The process can be divided into four sections: atomization of the fluid, mixing of the droplets, drying, and finally removal and collection of the dry particles.

In vertical spray driers, the flow of the drying gas may be concurrent or counter-current with respect of the movement of droplets. The movement of the gas is, however, complex and highly turbulent. Good mixing of droplets and gas occurs, and the heat and mass transfer rates are high. In conjunction with the large interfacial area conferred by atomization, these factors give very high evaporation rates. The residence time of a droplet in the drier is only a few seconds (5–30 s). Since the material is at wet bulb temperature for much of this time, high gas temperatures of 150–200°C may be used even with thermolabile materials. Although the temperature of the material rises above the wet-bulb temperature at the end of the process, the drying gas is cooler and the material is almost dry, a condition in which many materials are thermally less sensitive.

Drying is considered to take place by simple evaporation rather than by boiling and it has been observed that a droplet reaches a terminal velocity within about one foot of the atomizer. Beyond this, there is no relative velocity between the droplet and the drying gas unless the former is very large. The droplets may dry to form a solid, spherical particle. If, however, the emerging solids form a skin, internal pressure may inflate the particle and the final dry form will consist of hollow spheres which

may or may not have a blow hole. These xenospheres may also fragment, resulting in a final product of agglomerates of finely divided solids.

The capital and running costs of spray driers are high, but if the scale is sufficiently large, it may provide the cheapest method. When thermolabile materials are dried on a small scale, costs will be 10 to 20 times higher than for oven drying. Air used to dry fine chemicals or food products is heated indirectly, thus reducing thermal efficiency and increasing costs. In some other installations, hot gases from combustion may be used directly.

Drum driers

The drum drier consists of one or two slowly rotating, steam-heated cylinders. These are coated with solution or slurry by means of a dip feed in which the lower portion of the drum is immersed in an agitated trough of feed material or, in the case of some double-drum driers, by feeding the liquor into the gap between the cylinders. Spray and splash feeds are also used. In dip feeding, the hot drum must not boil the liquid in the trough. Drying takes place by simple evaporation rather than by boiling. The dried material is scraped from the drum by a knife at a suitable point.

Drying capacity is influenced by the speed of the drum and the temperature of the feed, which may be preheated. With the double-drum drier, the gap between the cylinders determines the thickness of the film.

Drum driers, like spray driers, are relatively expensive in small sizes and their use in the pharmaceutical industry is largely confined to drying thermolabile materials where the short contact time is advantageous. Drums are normally fabricated from stainless or chrome-plated steel to reduce contamination. The heat treatment to which the solid is subjected is more intense than in spray drying and the physical form of the produce is often less attractive during drying, the liquid approaches its boiling point and the dry solids attain the temperature of the drum surface.

SIZE REDUCTION AND CLASSIFICATION

The theoretical strength of crystalline materials can be calculated from interatomic attractive and repulsive forces. The strength of real materials, however, is found to be many times smaller than the theoretical value. The discrepancy is explained in terms of flaws of various kinds, such as minute fissures or irregularities of lattice structure known as dislocations. These have the capacity to concentrate the stress in the vicinity of the flaw. Failure

may occur at a much lower overall stress than is predicted from the theoretical considerations. Failure occurs with the development of a crack tip which propagates rapidly through the material, penetrating other flaws which may, in turn, produce secondary cracks. The strength of the material depends therefore on the random distribution of flaws and is a statistical quantity varying within fairly wide limits. This concept explains why a material becomes progressively more difficult to grind. Since the probability of containing an effective flaw decreases as the particle size decreases, the strength increases until, with the achievement of faultless domains, the strength of the material equals the theoretical strength. This position is not realized in practice due to complicating factors such as aggregation.

The strength of most materials is greater in compression than in tension. It is therefore unfortunate that technical difficulties prevent the direct application of tensile stresses. The compressive stresses commonly used in comminution equipment do not cause failure directly but generate by distortion sufficient tensile or shear stress to form a crack tip in a region away from the point of primary stress application. This is an inefficient but unavoidable mechanism. Impact and attrition are the other basic modes of stress application. The distinction between impact and compression is referred to later. Attrition, which is commonly employed, is difficult to classify but is probably primarily a shear mechanism.

The deformation and subsequent failure of a brittle material is not only a function of stress but also of the rate at which the stress is applied. Different results may be obtained from slow compressive breaking and impact breaking at the same energy level. Particle shape, size, and size distribution may be affected. In impact breaking, the rate of stress application is so high that the limiting strain energy may be exceeded several times by the suddenness of the operation. The reason is that fracture is time dependent, a lag occurring between the application of maximum stress and failure.

Stress application is further complicated by "free crushing" and "packed crushing" mechanisms. In free crushing, the stress is applied to an unconstrained particle and released when failure occurs. In packed crushing, the application of stress continues on the crushed bed of particles. Although further size reduction occurs, the process is less efficient due to vitiation of energy by the effects of interparticulate friction and stress transmission via particles which do not themselves fracture. This is easily demonstrated when a crystalline material is ground in a pestle and mortar. The fine powder initially produced protects coarser particles. If the material is sieved and

oversize particles are returned, the operation may be completed with far less effort.

Various hypotheses relate the net grinding energy applied to a process and the size reduction achieved. The first, proposed by Karl von Rittinger in 1867, states in Eq. 27 that the energy necessary for size reduction is directly proportional to the increase in surface area,

$$E = k(S_p - S_f) \quad (27)$$

where E is the energy consumed, and S_p and S_f are the surface area of the product and feed materials, respectively. The constant, k , depends on the grinding unit employed and represents the energy consumed in enlarging the surface area by one unit. The relation between surface area and particle size has already been derived, and Eq. 28 may therefore be written,

$$E = k \left(\frac{1}{d_p} - \frac{1}{d_f} \right) \quad (28)$$

where d_f and d_p are the particle sizes of feed and product particles, respectively.

The hypothesis indicates that energy consumption per unit area of new surface produced increases faster than the linear ratio of feed and product dimensions, a phenomenon already noted and explained. The proportionality of net energy input and new surface produced has been confirmed in some grinding operations.

Conversion of grinding energy to surface energy is neglected in Kick's law, promulgated in 1885. It is based on the deformation and brittle failure of elastic bodies and states that the energy required to produce analogous changes of configuration of geometrically similar bodies is proportional to the weight or volume of those bodies. The energy requirements are independent of the initial particle size and depend only on the size reduction ratio. Kick's law predicts lower energies than the relation proposed by Rittinger. The theory, however, demands that the resistance to crushing does not change with particle size. The role of flaws present in real materials is not considered, with the result that the energy required for fine grinding, when the apparent strength may have greatly risen, is underestimated.

A third theory of comminution gives results intermediate between the predictions of the laws of Kick and Rittinger (31). It rests upon three principles: the first states that any divided material must have a positive energy register. This can only be zero when the particle size becomes infinite. The input energy, E , for any size reduction process then equals the product energy register minus the feed energy register. The energy associated with a powder increases as the particle size decreases, and it

may be assumed that the energy register is inversely proportional to the particle size to an exponent, n . Hence, Eq. 29 is valid.

$$E = E_p - E_f = \frac{K}{d_p^n} - \frac{K}{d_f^n} \quad (29)$$

The second principle of this theory (31) assigns to n a value of i , stating that “the total work useful in breaking, which has been applied to a stated weight of an homogeneous material, is inversely proportional to the square root of the diameter of the product particles.”

The third principle states that breakage of the material is determined by the flaw structure. This aspect of size reduction has already been discussed.

A modification to Kick’s law, sometimes known as the fourth law of comminution, has also been proposed (32). For its discussion, the reader is referred to the original paper.

An empirical, but realistic approach to mill efficiency is gained through experiments in which the energy consumed and size reduction achieved are compared with values obtained in a laboratory test operating under free crushing conditions. All energy supplied in the latter is available for crushing and the test is assumed to be 100% efficient. Both slow crushing and impact tests are used. A large number of single particles may be simultaneously crushed and the work done is measured (33). The latter is related to the size reduction. Similar measurements can be made during practical milling, expressing the efficiency of the process as a percentage of the free crushing value. On this basis, the approximate efficiency of the roll crusher is 80%, of the swing hammer mill 40%, of the ball mill 10%, and of the fluid energy mill only 1%.

The Operation of Mills

Heywood (34) has stated that any type of crushing or grinding machine exhibits optimal comminution conditions for which the ratio of the energy to new surface is minimal. If finer grinding is attempted in such a machine, the ratio is increased. Mills may thus become grossly inefficient if called upon to grind at a size for which they were not designed. A limited size reduction ratio is imposed upon a single operation, larger ratios being obtained by the adoption of several stages, each employing a suitable mill. The fluid energy mill, which presents a size reduction ratio of up to 400, is exceptional.

A low retention time is inherent in free crushing machines. Little overgrinding takes place and the production of excessive undersize material or fines is avoided. Protracted milling times are found with many

low-speed mills, with the result that considerable overgrinding takes place. Accumulation of product particles within the mill reduces the effectiveness of breaking stresses and the efficiency of milling progressively decreases.

Dry and wet grinding

Between the approximate limits of 5 and 50% moisture, materials cake and do not flow. Both factors oppose effective grinding. Dry grinding is carried out at low moisture contents, the upper limit depending on the nature of the material. Although 5% or more moisture may be permissible for vegetable drugs, it would prove excessive during the milling of a coarse, impervious solid.

Wet grinding is a common procedure when a fluid suspension is required and drying, which would provide a significant drawback, is unnecessary. An excellent dispersion can be produced simultaneously, which in some operations provides the primary objective, size reduction being of secondary importance. Wet grinding also may be adopted when the size reduction achieved during dry grinding is prematurely linked by aggregation.

Certain general advantages are secured during wet grinding, including increased mill capacity, a lower energy consumption, the elimination of hazards from dust, and easier handling of materials. The principal disadvantage, apart from the possible inclusion of a drying stage, is the increased wear of the grinding medium.

Temperature sensitivity

Care must be exercised during the milling of temperature-sensitive materials, especially for a very fine product; caking results if the softening point is exceeded. Materials may be chilled before grinding or facilities provided for cooling the mill during grinding. Waxy solids can be successfully ground with dry ice, the low temperatures conferring brittle characteristics on the material. Chemical degradation may occur at high grinding temperatures. Oxidative changes can be prevented by grinding in an inert atmosphere such as nitrogen.

Structural changes

Several examples of change of physical structure during very fine grinding have been reported, for example, changes in the crystal form of calcium carbonate after ball milling (35), distortion of the kaolinite lattice (36), and formation of various barbiturate polymorphs (37). Changes such as these could affect solubility and other physical characteristics which, in turn, might influence formulation and therapeutic value.

Dust hazards

Hazards from dust may become acute during dry grinding. Extremely potent materials require dust proofing of machines and dust-proof clothing and masks for operators. Danger may also arise from the explosive nature of many dusts.

Grinding Equipment

The following equipment are in regular use for dry-grinding pharmaceutical materials: edge- and end-runner mills, hammer mills, pin mills, ball mills, vibratory mills, fluid energy mills, colloid mills, and roller mills.

Classification or Size Separation

Although a number of particle properties can be used to classify a powder, only two are important. The first is based on the ability of a particle to pass through an aperture. This is sieving or screening. The second employs the drag forces on a particle moving through a fluid. The term “classification” is sometimes restricted to this method of separation but here the terms “elutriation” and “sedimentation” are used. In general, screening is applied to the separation of coarse particles and sedimentation to the separation of fine particles.

Sieving and screening

Sieves and screens are widely used for the classification of relatively coarse materials. For very large particles (>0.5 in.) a robust plate perforated with holes is used. However, the pharmaceutical applications of screening are for much smaller particles and screens are in the form of woven meshes. Unless special methods are used to prevent clogging and powder aggregation, the lower useful limit is in a cloth woven with 200 mesh/in. (70–80 μm). Fine screens of this type are extremely fragile and must be used with great care.

As the scale of the operation increases it becomes, in general, less precise. For continuous screening, the feed material is made to move across the screen to a point of discharge. The residence time on the screen is usually short and many undersize particles traverse it without falling through. With an increase of sieving area, the meshes become more fragile and the finest meshes must be supported with a coarser wire. An example of a large-scale separator utilizes a circular screen, up to 5 ft (1.5 m) in diameter, vibrated in a horizontal plane, the gyratory movement being imparted by an out-of-balance fly wheel connected to the assembly. In other machines, the mesh is rectangular and inclined at a shallow angle (5–30°).

A gyratory movement is developed and the material to be classified is fed to the top. These machines may bear more than one deck, thus allowing the separation of the powder into several fractions at one time.

Elutriation and sedimentation

The simplest classifier is a rising current of fluid in which the particles are suspended. In this case, the force opposing the upward drag is gravitational. If the opposition develops a terminal velocity higher than the current speed, the particle falls. This is the principle of elutriation; the particle size d at which the separation is made follows from a rearrangement of Eq. 29 for conditions in which Stokes' law is valid; it is given by Eq. 30,

$$d = \sqrt{\frac{18\eta\mu}{(\rho_s - \rho)g}} \quad (30)$$

where $\rho_s - \rho$ is the density difference between solid and fluid, η is the viscosity of the fluid, and μ is the speed of the upward current.

In practice, fluctuations in flow conditions due to natural convection and a violation of the conditions for which Stokes' law is valid, blur the point of separation.

The centrifuge is normally operated to completely separate two phases. If, however, the rate at which the feed passes through does not allow all particles to settle, the action of a classifier is developed. This is illustrated by a solid-bowl centrifuge which consists of a steel shell in the form of a frustum mounted horizontally. It contains a conveying screw at the wall which rotates at a slightly higher speed than the shell. Particles that settle at the wall are conveyed to the narrow end of the shell and discharged. Fine particles are entrained with the overflow to the other end. Further details of this and other centrifugal classifiers have been given by Treasure (38).

MIXING

Mixing has been defined (39) as an operation in which two or more ingredients in separate or roughly mixed condition are treated so that each particle of any one ingredient is adjacent to a particle of each of the other ingredients, as nearly as possible. The term “blending” is synonymous and “segregation” or “demixing” is the opposite.

Mixing has been classified (40) as follows:

- *Positive mixing* which applies to systems that, given time, would spontaneously and completely mix. Examples are provided by two gases or two miscible

liquids; mixing apparatus is used on such systems to accelerate mixing.

- *Negative mixing* is demonstrated by suspensions of solids in liquids. Any two-phase system in which the phases differ in density separates unless continuously agitated.
- *Neutral mixing* occurs when neither mixing nor demixing takes place unless the system is acted upon by a system of forces. Examples are found in the mixing of solids and of solids with liquids when the concentration of the former is high.

Theoretical knowledge is, however, insufficient to predict the performance of mixers. More commonly, choice is based upon broad empirical principles which are supported by practical tests.

Mixing of Solids

The mixing of all systems of matter involves a relative displacement of the particles, whether they are molecules, globules, or small crystals, until a state of maximum disorder is created and a completely random arrangement is achieved.

In 1953, Lacey (41) showed that the variation in the composition of samples drawn from a random mixture of two materials could be expressed by Eq. 31,

$$s = \sqrt{\frac{p(1-p)}{n}} \quad (31)$$

where s is the standard deviation of the samples, p is the proportion of one component, and n is the number of particles in the sample. The relation requires that the two components are alike in particle size, shape, and density and only can be distinguished by some neutral property, such as color. If very many samples are withdrawn from a mixture of equal parts of two materials, each containing a given number of particles, the results of analysis can be presented in the form of a frequency curve in which the samples are normally distributed around the mean content of the mixture, and 99.7% of the samples will fall within the limits $p = 0.5 \pm 3\sigma$. The standard deviation of the samples is inversely proportional to the square root of the number of particles in a sample. If the particle size is reduced to the extent that the same weight of sample contains four times as many particles, the standard deviation is halved.

In a critical examination of pharmaceutical mixing, Train (42) showed that samples of a random mixture of equal parts A and B must contain at least 800 particles if 997 out of every 1000 samples were to lie between $\pm 10\%$ of the stated composition, that is, the proportion, p , of

$A = 0.5 \pm 0.05$, where $\sigma = 0.05/3$. If limits of $\pm 1\%$ were substituted, 90,000 particles must be present in each sample. The true standard deviation is given by σ . The standard deviation estimated by the withdrawal of a number of samples is denoted as s .

If, instead of equal parts A and B, the proportion of an active ingredient, A, in the mixture was 0.1 (10%), imposition of limits of $\pm 10\%$ (in 997 cases out of 1000) requires that each sample shall contain over 8000 particles. If the proportion of active constituent is 0.01, or 1%, a figure of 90,000 particles per sample is obtained, and if the limits are reduced to $\pm 1\%$, the active constituent is 0.01, or 1% a figure of 90,000 particles per sample is obtained, and if the limits are reduced to $\pm 1\%$, the figure is 9×10^6 .

The theoretical derivation of these results is based on component particles which vary in size, shape, and density. This condition is not encountered in the practical mixing of solids and, as described later, any of these factors may prevent the formation of a random mixture. The value of the number of particles per sample derived in any example must therefore be raised if the limits given are to be maintained.

As already shown, a series of samples drawn from a random mix exhibits a standard deviation of s_r . An index of mixing, M , suggested by Lacey (43) is given by Eq. 32,

$$M = \frac{s_r}{s} \quad (32)$$

where s is the standard deviation of samples drawn from the mixture under examination. This approaches unity as mixing is completed. Eq. 33 has been suggested,

$$M = \frac{s_0 - s}{s_0^2 - s_r^2} \quad (33)$$

where s_0 is the standard deviation of samples drawn from the unmixed materials. It is equal to $p(1-p)$, where p is the proportion of the component in the mix. It has been modified (43) to Eq. 34, using the variance of the samples,

$$M = \frac{s^2 - s_r^2}{s_0^2 - s_r^2} \quad (34)$$

This is a fundamental equation for expressing the state of the mixture, the index M varying from zero to one.

The binomial and Poisson distributions have also been used to examine the state of a mixture. If the proportion of black particles in a random mixture of black and white particles is p , the probability, $P(x)$, of obtaining x black particles in a sample of n particles is given by Eq. 35.

$$P(x) = \binom{n}{x} p^x (1-p)^{n-x} \quad (35)$$

If p is small (<0.15) and n is large, the Poisson distribution can be used, applying Eq. 36,

$$P(x) = e^{-m} \frac{m^x}{x!} \quad (36)$$

where $m = np$, the mean number of black particles in the samples of n particles. This relation may be used in an assessment of dry mixing equipment (44). If m is greater than 20 and more than 10 samples are taken, then:

- About 10 of the samples have the number of black particle's outside the limits $m \pm 1.7\sqrt{m}$,
- About 5% of the samples have the number of black particles outside the limits $m \pm 2.0\sqrt{m}$, and,
- About 1% of the samples has the number of black particles outside the limits $m \pm 2.6\sqrt{m}$.

Mechanism of mixing and demixing

The randomization of particles by relative movement, one to another, is achieved by the following mechanisms:

- *Convective mixing*, where groups of adjacent particles are transferred from one location in the mass to another.
- *Diffusive mixing*, where the particles are distributed over a freshly developing surface, and
- *Shear mixing*, where slip planes are set up within the mass.

Convective mixing predominates in machines utilizing a mixing element moving in a stationary container, for example, the horizontal ribbon mixer. Groups of adjacent particles are moved from one position to another, steadily decreasing the scale of segregation.

Diffusive mixing predominates in tumbler mixers. The material is tumbled as it is lifted past its angle of repose. Mixing occurs when a particle changes its path of circulation through a collision or by being trapped in voids presented by another layer of particles.

Shear mixing occurs when forces acting on the particles induce the formation of a slip place, resulting in relative displacement of two regions. Shear mixing occurs, for example, in the rearrangement of shapes as the main charge falls from end to end in a double cone mixer. Train (42) has stressed the importance of expansion or dilation of the material so that shear forces may be effective. A practical corollary is that efficiency will be reduced if the machine is overfilled.

As long as one type of particle is not preferentially caught, random mixing eventually occurs in the radial plane. If, however, one component is smaller, denser, or has certain shape characteristics, it is preferentially trapped and moves into the lower layers of the mixing zone until it finally concentrates as a central core running

the length of the mixer. Similar effects occur in axial mixing, and the final shape of the segregated zone formed under the influence of axial and radial movement depends on the flow properties of the material. Similar effects have been reported with a double-cone blender (44). Segregation also occurs with materials dumped from the mixer.

Mixing rate

Because mixing is a process of achieving uniform randomness, the rate of mixing is proportional to the amount of mixing still to be done. If, at the start a particle changes its path of circulation, it is most likely to find itself in a different environment. The mixing rate is therefore high. At the end of the process, the particle is less likely to find a different environment, and such a change gives no useful mixing. Fewer mixing events take place, and the mixing rate finally reaches zero. It can be represented for any mixing mechanism by Eq. 37,

$$\frac{dM}{dt} = k(1 - M) \quad (37)$$

where M , the index of mixing, has already been defined. Integration of Equation (37) gives Eq. 38.

$$M = 1 - e^{-kt} \quad (38)$$

The rate constant, k , depends on the physical nature of the materials being mixed and on the geometry and operation of the mixer.

Mixing Machines

Trough and ribbon mixers

A simple trough mixer consists of a semicircular trough in which an impeller, such as a number of paddles mounted at diverse angles on a shaft running the length of the trough, rotates, lifting and distributing the material in an irregular manner. Convective and shear mixing occurs, as well as some fine-scale diffusive mixing when the impeller lifts material clear of the main charge.

The ribbon mixer employs a ribbon-like conveying scroll. The helix, which may be continuous or interrupted, is rotated in a semicircular trough and mixing again occurs through convection and shear, giving rapid coarse-scale dispersion. Two ribbons set to convey material in opposite directions are frequently fitted to the shaft. Although little axial mixing in the vicinity of the shaft occurs, mixtures with high homogeneity can be produced by prolonged mixing, even when components differ in particle size, shape, or density or tend to aggregate.

Tumbler mixers

Tumbler mixers operate primarily by a diffusive mechanism; their use is confined to freeflowing and granular materials. The mild forces are employed, which preclude the mixing of materials that aggregate strongly, allow friable materials to be handled satisfactorily. The more elaborate geometrical forms are most commonly used because movement of material in all planes, which is necessary for rapid overall mixing, is induced. Internal baffles and lifter blades may also be incorporated. For example, axial movement of material along the length of a simple drum mixer is slow and can be enhanced by these methods.

Mixing of Liquids

Miscible liquids are most commonly mixed by impellers rotating in tanks, including paddles, propellers, and turbines. All the material should pass through the impeller zone at frequent intervals of time, the design of the mixer preventing the formation of “dead” zones. The turbulent, high velocity flow of liquid from the impeller causes mixing by projecting eddies into, and entraining liquid from, the neighboring zones. The thin ribbons of one component in another rapidly become diffuse and finally disappear through molecular diffusion.

The flow pattern may be analyzed in terms of its three components of motion:

- Radial flow, in a direction perpendicular to the impeller shaft.
- Longitudinal or axial flow, in a direction parallel to the shaft, and
- Tangential flow, in which the liquid follows a circular path around the shaft.

A satisfactory flow pattern depends on the correct balance of these components. In a cylindrical tank, radial flow gives rise to axial flow by reaction at the wall of the tank. Tangential flow receives no such modification. Its predominance as laminar flow circulation supports stratification at various levels. Furthermore, a vortex is created at the surface of the liquid which may penetrate to the impeller, causing air to be dispersed in the liquid. In general, tangential flow should be minimized by moving the impeller to an off-center position, thus destroying the symmetry of the mixer, or by modification of the flow pattern by means of baffles. Tanks with vertical agitators may be baffled by one, two, or more strips mounted vertically on or just away from the vessel wall. These reduce but do not eliminate tangential flow, whereas little modification of radial and axial flow occurs. Baffles produce additional turbulence.

Paddle mixers

For a simple paddle, with upper and lower blades, suitable for mixing miscible liquids of low viscosity a tangential flow pattern predominates with zones of turbulence to the rear of the blades (10–100 rpm). The gate paddle is suitable for mixing liquids of higher viscosity and the anchor paddle with low clearance between pan and blade is useful for working across a heat transfer surface. Stationary paddles intermeshing with the moving element suppress swirling in the mixer. In other examples, baffles are also necessary. Unless paddle blades are pitched, poor axial turnover of the liquid occurs. Paddles are therefore not suitable for mixtures that separate.

Propeller mixers

Propellers are commonly used for mixing miscible and immiscible liquids of low viscosity. The marine propeller is typical of the group. High speed rotation (400–1500 rpm) of the relatively small element provides high shear rates in the vicinity of the impeller and a flow pattern with mainly axial and tangential components. They may be used in unbaffled tanks when mounted in an off-center position or inclined from the vertical. In large-scale operations, horizontal mounting in the side of the vessel is frequently used.

Turbines

Turbine designs are intermediate between paddles and propellers. Turbines are effective mixers over a wide viscosity range and provide a very versatile mixing tool. The ratio of radial to tangential flow, the predominating parameters with this impeller, increases as the operating speed increases. Pitched-blade turbines are sometimes used to increase axial flow. Baffles must be used to limit swirling unless the turbine is shrouded. This impeller produces a discharge with no tangential component.

STERILIZATION

Sterilization processes do not result in a product that can be described as absolutely sterile or nonsterile inasmuch as the process is a statistical phenomenon. A variety of techniques are available (45), including heat, radiation, ethylene oxide sterilization, and sterile filtration.

Thermal Sterilization

The amount of heat required to sterilize depends upon the magnitude (T), duration (t), and amount of moisture

present, $t \propto 1/T$. For example, heat coagulates protein in the living cell. The temperature required for this phenomenon to occur is inversely proportional to the moisture present.

Dry heat

Relatively stable substances that resist degradation at high temperatures ($>140^\circ\text{C}$) are suitable candidates for dry heat sterilization. A 2-h exposure at 180°C or 45 min at 260°C kills spores as well as vegetative forms of micro-organisms. These exposure periods do not include the lag time from loading of the oven until sterilization temperature is reached. The lag time depends on the geometry and operating features of the oven and the characteristics of the load.

Both natural and forced-convection oven types can be employed; they have been described in the section on drying. The forced-convection oven offers the advantages of uniformity of heat distribution and reduction in lag time in comparison with the natural-convection system. The dry-heat method is reserved almost exclusively for glass or metal as other materials char (cellulose), oxidize (rubber), or melt (plastic) at these temperatures.

Moist heat

Moist heat offers the advantage of greater effectiveness at low temperatures. The thermal capacity of steam is much greater than that of hot air. Spores and vegetative forms of bacteria may be effectively destroyed in an autoclave employing steam (121°C) under pressure (15 psig) for 20 min or (27 psig at 132°C), for 3 min. The lag time to complete exposure of the material to be sterilized is important.

Radiation

Ultraviolet light is frequently employed to reduce airborne microbial contamination. Surface sterilization is usually achieved by employing a mercury vapor lamp with an emitted light of 253.7 nm.

Radiation sterilization includes the use of the ionizing radiation of x-rays and gamma-rays. The former are derived from bombardment of a heavy metal target with electrons. Gamma-rays are obtained from atomic nucleus decay from excited to ground state.

The energy evolved from radiation can be equated to photon behavior where $E = h\nu$ and $\nu = C/\lambda$, (E and ν are the energy and frequency of a photon, respectively), h is Planck's constant, and C and λ are the speed and wavelength of light, respectively. The energy absorbed from the radiation sources equates to the dose.

$$1 \text{ rad} = 100 \text{ erg/g of material absorbing}$$

$$= 6.24 \times 10^{13} \text{ eV/g}$$

$$= 2.4 \times 10^{-6} \text{ cal/g} (10 \times 10^{-6} \text{ J/g})$$

There are a variety of radiation sources. ^{60}Co decays to ^{59}Co in the core of a nuclear reactor to emit two photons (1.17 and 1.33 MeV) and an electron (0.31 MeV). The half-time for decay is 5.3 years. ^{137}Cs decays emitting one photon (0.661 MeV). Cesium has a 33-year half-life. An electron beam can be accelerated to an energy equivalent of 5–10 MeV. At energies below 5 MeV, penetration is insufficient for sterilization. Depth of penetration can be correlated with energy levels; for example, materials with density equivalent to water ($\rho = 1 \text{ g/cm}^3$) are penetrated 0.5 cm/MeV. ^{60}Co gives rise to radiation that penetrates 30 cm through water. Accelerating electrons have a high dose rate and exposure is only required for seconds. ^{60}Co has a lower dose rate, and an exposure for hours is required.

Ionizing radiation arises from the photoelectric effect, the Compton effect, or ion pair production. Gamma radiation causes local and intense damage and may break chemical bonds. The primary target is the deoxyribonucleic acid (DNA) of the micro-organism. In addition, free radicals may be formed, such as peroxides that result in intracellular and extracellular peroxides by a chain reaction that causes damage.

Resistance to damage

Damage depends on the amount of energy absorbed relative to the number and resistance of the micro-organisms being irradiated. Unicellular organisms have greater resistance than multicellular ones. Gram-positive bacteria have greater resistance than gram-negative bacteria. Finally, bacterial spores have greater resistance than vegetative forms. Viruses are more resistant than bacteria. The energy required to reduce the population of viruses by 90% (D value), is 0.5 Mrad (5 mGy). Fungi are equivalent to bacterial spores in their resistance.

In order to evaluate the dose, a number of parameters must be known. What magnitude of source (e.g., ^{60}Co) is available? A typical source ranges from 500,000 to 2×10^6 Curies (Ci) where 1 Ci is 3.7×10^{10} disintegrations per second. The product geometry and the speed of the conveyor carrying it to the source must be known. The dose can be evaluated by a variety of dosimetric techniques. In bulk or ampoules containing liquids, ferric ammonium sulfate and ceric sulfate can be used and the absorbance change evaluated by UV spectrophotometry; however, this is only accurate for ^{60}Co and ^{137}Cs .

Radiochromic solids can be utilized and evaluated by visible spectrophotometry. Amber and red polymethyl methacrylate are used to evaluate 0.1–1.0 Mrad and 0.5–5.0 Mrad, respectively. Nylon film is examined for opacity following exposure and may be used to evaluate exposures of 0.1–5.0 Mrad.

Validation requires the determination of the bioburden and the *D* value. These represent the dose required to achieve sterilization and the estimated dose. If low *D* values are obtained, the dose may be regarded as overkill. *Bacillus pumulis* exhibits inherently high resistance to gamma-ionization radiation (*D* values 0.15–0.22 Mrad). The FDA prefers a 12-log reduction in microorganisms. The dose required is approximately 2.6 Mrad.

Ethylene Oxide

Ethylene oxide (bp, 10.8°C) is a gaseous alkylating agent. It alkylates proteins and ribonucleic and deoxyribonucleic acid in micro-organisms. It replaces labile hydrogen with hydroxyethyl groups. Ethylene oxide is utilized as a surface sterilant. Bulk crystalline materials can occlude vegetative bacterial cells or spores with crystals. Consequently, ethylene oxide does not reach them. The final step prior to sterilization is an aseptic recrystallization step.

Ethylene oxide is a colorless gas with an aromatic odor. The threshold limit for the odor is 700 ppm. The OSHA specification for worker exposure is 10 ppm. The toxicity of ethylene oxide is similar to that of ammonia. It causes conjunctival and respiratory irritation, dizziness, headaches, and vomiting. It is known to be mutagenic and may be carcinogenic. By-products include ethylene glycol (bp, 198.9°C) and ethylene chlorhydrin (bp, 128.4°C). Pure ethylene oxide is flammable and explosive. It is generally mixed with propellant (88:12) or carbon dioxide (90:10). Ethylene oxide polymerizes in the liquid state in 90–120 days. In this form it may plug lines or deposit polymerized sludge.

Ethylene oxide inactivates all micro-organisms. The sterilizing rate depends upon its concentration, the temperature, the duration of exposure, and the water content of the micro-organism. Inactivation follows classical first-order kinetics and is irreversible. Relative humidity is synergistic, at 30–60% the micro-organism hydrates. The water acts as a vehicle to transport the gas through polyethylene and polypropylene. Polystyrene traps ethylene oxide and dissipates it over years and thus is not appropriate for ethylene oxide sterilization. Temperatures of 40–60°C are suitable for heat-sensitive articles. Cycle times are longer at low temperatures, relative humidities, or ethylene oxide concentrations.

Generally, concentrations of 350–700 mg/ml are employed; cycle times vary from 4 to 12 h.

Following sterilization the load is degassed by a dynamic process wherein filtered air is passed over the product for 12–72 h. Degassing usually takes place in the treatment chamber but may be moved to a sterile facility. The process is monitored using *Bacillus subtilis* var. *niger* as a biological indicator, commercially available as spore strips (10^6 spores per strip). In addition, the load is probed with thermocouples during validation. The gaseous mixture is sampled at different points in the sterilizer for gas chromatographic analysis.

Sterile Filtration

Several filter geometries are available for sterile filtration. They consist of flat membranes in a stainless steel press (<293 mm), pleated membranes housed in stainless steel cartridges, and stacked plates in the form of flat segments of membrane filters.

Matrix filters consist of fibers with pores having a depth up to 120 μm . Cellulose nitrate may be dissolved in a highly volatile solvent, such as amyl acetate, ether, or dioxane. A gel-forming solvent, acetone, ethanol, or propanol, may be added. The mixture is poured on a flat plate and placed in a controlled-temperature environment to dry. Pore size is dependent on the concentration of the gel-forming solvent. A number of other substances may be used as filter material, including cellulose, acetate and butyrate, polyamides (nylon), polysulfones, fluorocarbons (Durapore membranes), polyvinylidene difluoride (hydrophobic), or surfaces modified with organic amides (hydrophilic), acrylic polymers, or polyvinyl chloride. To make some membranes hydrophilic, surfactants may be added including Tween 80, Triton X-100, hydroxypropyl cellulose, or glycerol. Sieve filters are made of polycarbonate (Nucleopore, 10 μm thick). Collimated uranium fission products form nucleation tracks in film. Exposure to chemical etching determines the pore size.

Adsorption and screening

Most membrane filters, when wetted, have a negative charge. Bacteria have a similar negative charge and do not necessarily remain on the filter. Filters with other characteristics can be selected under these circumstances. Positively charged (AMF Zeta Plus Membrane) or protein- and peptide-adsorbing (Pall Posidyne Nylon 66) filters can be selected.

Ionic strength, pH, pressure, and flow rate affect particle adsorption. The flow rate through a filter is expressed by Eq. 39,

$$Q = \frac{C_i A P}{V} \quad (39)$$

where C_i is the inherent resistance of the filter to flow (a function of void volumes), A is the surface area, P is the pressure, and V is the viscosity. Filters are rated according to nominal pore size and absolute pore size (the largest pore in the filter); this recognizes that a pore size distribution exists.

Filter integrity

The filter integrity can be evaluated by a number of techniques. The destructive test involves filtering a suspension of bacterial cells (*Pseudomonas diminuta*, $0.3 \times 1 \mu\text{m}$, through a $0.2 \mu\text{m}$ -filter. If 6 L of suspension containing 1×10^7 organisms per mL are passed through a $1\text{-}\mu\text{m}$ filter, there should be no microorganism and an 8-log reduction would have occurred. The bubble-point test assumes that pores can be characterized as capillaries. When totally wetted, all the capillaries should be full of water or solution. The pore length is generally much greater than the diameter. Pressure is applied to the wetted filter. The bubble-point pressure, P , may be described by Eq. 40,

$$P = \frac{4\gamma \cos \Theta}{D} \quad (40)$$

where γ is the surface tension (72 dynes/cm² or 7.2 Pa), θ is the contact angle, and D is the diameter of capillary. The bubble-point test is performed before and after sterile filtration.

A specified area of filter must be soaked in a specified volume of product for a designated time. The accelerated stability of active ingredients at 40–60°C for 60 days must be established prior to the selection of a filter for a particular purpose. The extent of damage, and the nature and quantity of extractables and their potency have to be evaluated.

EXTRACTION AND LEACHING

Leaching or solid–liquid extraction are terms that describe the extraction of soluble constituents from a solid or semisolid by means of suitable solvents. The process, which is used whenever tea or coffee is made, is an important stage in the production of many fine chemicals found naturally in animal and vegetable tissue. Examples are found in the extraction of fixed oils from seeds, in the preparation of alkaloids, such as strychnine from *Nux vomica* beans or quinine from Cinchona bark; and in the isolation of enzymes, such as rennin, and hormones, such as

insulin, from animal sources. In the past, a wider importance attended the process because the products of simple extraction procedures, known as galenicals, formed the major part of the ingredients used to fulfill a doctor's prescription.

Whatever the scale of the extraction, leaching is performed in one of two ways. In the first, the raw material is placed in a vessel, forming a permeable bed through which the solvent or menstrum percolates. The wanted constituents are dissolved, and the solution issues from the bottom of the bed. This liquid is sometimes called the miscella and the exhausted solids, the marc. The process is called leaching by percolation. The second process employs immersion and consists of immersing the solid in the solvent and stirring. After a suitable period of time, solid and liquid are separated.

Percolation

Coarsely ground material is placed in the body of the extractor which may be jacketed for control of the extraction temperature. The packing must be even or the solvent flows preferentially through a limited volume of the bed and leaching is inefficient. In large extractors, channeling is prevented or reduced by horizontal, perforated plates placed at intervals in the bed; these redistribute the percolating liquid.

Solvent inhibition swells dried materials and reduces the permeability of the bed. This is most marked with aqueous solvents. If swelling occurs, it is necessary to moisten the material with water or with the solvent before it is packed into the extractor.

Immersion

In pharmaceutical processes, leaching by immersion is carried out in simple tanks which may be agitated by a turbine or paddle. If the solids are adequately suspended, intimate contact between the phases promotes efficient extraction. Incomplete extraction due to channeling is avoided and difficulties due to swelling do not arise. Problems arise, however, in the subsequent separation of the phases. The materials to which leaching by immersion is applied are normally either finely divided or coarse and compressible. When agitation ceases, the solids settle and the leach liquid can be siphoned or pumped off by lines suitably placed in the tank. The sediment, however, contains a large volume of the leach liquid which must be recovered by resuspending the solids in fresh solvent, allowing the solids to sediment and decanting the supernatant liquid. Cake filtration provides an alternative

method of separation. The leach liquid remaining in the cake is displaced by passing a wash liquid. In some cases, a filter press may be used for both extraction and separation.

Solvent

The ideal solvent is cheap, nontoxic, and nonflammable. It is highly selective, dissolving only the wanted constituents of the solid. It should have a low viscosity, allowing easy movement through a bed of solids, and, if the resulting solution is to be concentrated by evaporation, have a high vapor pressure. Water and alcohol, and mixtures of the two, are widely used. Both, however, are nonselective, leaching varying proportions of gums, mucilages, and other unwanted components. Most of the tinctures and liquid extracts used in pharmacy are simple, impure extracts made with, water or mixtures of water and alcohol. Acidified or alkaline mixtures of water and alcohol are used to extract insulin from comminuted pancreas. A more selective extraction is given by petroleum solvents, benzene, and related solvents. In the preparation of many pure alkaloids, the powdered material is moistened with an alkaline solution, packed into a bed, and leached with petroleum. Subsequent purification by fractional crystallization is facilitated by the absence of gums. Acetone and chlorinated hydrocarbons also find applications in leaching. In some cases, specific properties of the wanted constituents may suggest a particular solvent. Eugenol, for example, can be readily extracted from cloves with a solution of potassium hydroxide.

Leaching Rate

Whatever method is adopted, leaching consists of a number of consecutive diffusional or mass transfer processes. The solvent first penetrates the raw material and dissolves the soluble elements. These diffuse in the opposite direction to the surface of the solid matrix and through the liquid layers at its surface to reach the bulk solution. These processes are under the influence of an overall concentration gradient, the concentration being lowest in the bulk solution. Any of these processes may be responsible for limiting the rate at which leaching proceeds. In pharmaceutical leaching, however, the solid matrix is usually cellular, a structure which normally offers the highest diffusional resistance. The complexity of such structures does not permit a strict analysis of the processes of mass transfer. Nevertheless, the simple diffusional concepts expressed in Fick's law suggest that the following factors influence the leaching rate:

- The size distribution of the leached particles,
- The temperature of leaching,
- The physical properties of solvent, and
- The relative movement imposed upon the solids and the liquid.

Size and Size Distribution of the Solid Particles

The particle size of the solids determines the distance which solvent and solute must diffuse within the solid matrix. Since this distance offers the major diffusional resistance, its reduction by comminution raises the rate of leaching, the concentration gradient being effectively increased. In addition, the inverse relationship between particle size and surface area requires an increase in the area of contact between the matrix and the surrounding liquid. Transfer of solute at this boundary is therefore facilitated. In leaching by immersion, a further advantage conferred by size reduction is the ease with which finer particles are suspended. Finally, extensive cell rupture occurs during grinding, allowing more direct contact between solvent and solute and more rapid dissolution and diffusion.

Other factors, however, operate against size reduction. Leaching by percolation demands the formation of a permeable bed. Low permeability gives low flow rates and low extraction rates. Permeability is a complex function of both particle size and porosity, the former determining how a given void space is to be disposed within the bed. The disposition of the void space consists of few channels of relatively large diameter, that is, a bed of high permeability, if the particle size is large. In leaching by immersion, the difficulties of separating solid and liquid increase as the particle size decreases.

The opposition of the factors suggests an optimum particle size for any particular extraction. This is determined to some extent by the physical nature of the solids. A dense, woody structure would be extracted as a fine powder. An example is given by the root of *Ipecacuanha*. A leafy structure, on the other hand, would be more satisfactorily leached as a coarse powder.

Both porosity and permeability are influenced by the particle size distribution. A high porosity is secured if the distribution is narrow. Small particles may otherwise fill the interstices created by the contact of larger particles. After grinding it is often necessary, therefore, to classify the product and remove undersize material. This material would then be bulked with the fines from other batches and extracted separately. A further advantage arising from a narrow size distribution is even packing and the creation of a regular system of pores and waists. This promotes even movement of solvent and solution through the bed.

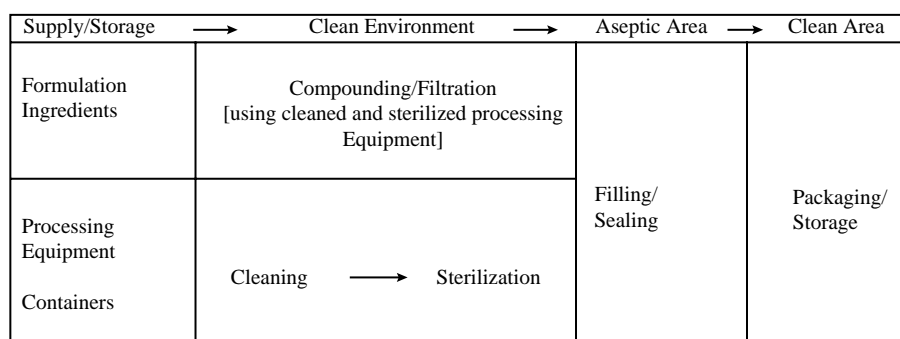

Fig. 6 Flow diagram illustrating the various processes in sterile parenterals production.

Temperature

Within the limits imposed by the thermal stability of the wanted constituents, a high extraction temperature appears desirable. The solubility of most materials increases with increasing temperature, allowing higher solute concentrations and higher concentration gradients. Both this and the increased diffusivity result in higher extraction rates. In many cases, however, materials are susceptible to heat degradation and cold extraction must be used. In addition, the selectivity of a solvent may be impaired at high temperatures. An example of the use of moderately high temperatures is the extraction of Rauwolfia alkaloids with boiling methanol.

The Relative Movement Imposed Upon the Solids and the Liquid

The major and controlling resistance to the diffusion of the solute to the bulk solution is normally found in the cell matrix. Increase in the rate of movement of the solution past the surface does not, therefore, greatly affect the rate of extraction. This is in marked contrast to the processes of dissolution and crystallization. Nevertheless, movement is imposed upon the solvent in both general methods described above.

In the percolation of a liquid through a bed of solids, mass transfer of the solute from the surfaces of the solid to the liquid in the interstices of the bed takes place by molecular diffusion and by natural convection arising from the density changes created by dissolution. Although these processes are slow, they are much faster than mass transfer in the matrix under the same concentration differences. Concentration gradients in the liquid outside the particles are, therefore, very low. At any point in the bed, the introduction of dilute solution from above and the loss of concentrated solution to below decrease the interstitial concentration by dilution or displacement. This effect can be considered simply to reduce the solute concentration at

the junction of solid and solution, thus imposing a favorable concentration gradient within the matrix.

APPLICATIONS

The processes described here are integrated in order to facilitate the production of pharmaceutical dosage forms. The following examples are intended to illustrate the application of the processes in the dominant pharmaceutical settings. They have been selected to demonstrate the broad application of unit operations in pharmaceutical manufacturing. Unique processes are associated with each dosage form. This is no less the case for dermatologics, intranasal and inhalation products, and the range of alternative pharmaceuticals than for the examples given. Nevertheless, the majority of processes and their underlying principles (11) are similar from one dosage form to the next.

Parenteral Products

Parenteral products are intended for injection into a variety of subdermal and submucosal locations (46). Their manufacture can be defined as a sequence of operations intended to be performed in certain environments or under specific conditions. Fig. 6 illustrates the sequence in which these processes may be combined. This flow diagram shows the relationship of the unit operations to the underlying physical-organic chemistry of compounding and the subsequent processes pertaining to packaging.

Solid Dosage Forms

The majority of solid dosage forms are intended for oral ingestion. The drug released from the dosage form is available at the site of absorption or action within the gastrointestinal tract.

Fig. 7 Sequence of events in tablet press operation.

Additional processes are required for the production of tablets beyond those described previously. As these processes are not ubiquitous in pharmaceutical manufacturing they are dealt with only briefly here.

Granulation

Following particle size reduction and blending the formulation may be granulated (47), which provides

homogeneity of drug distribution in the blend. In addition, it may help flow properties and compression characteristics of the powder. Large granules can be prepared from primary particles by drying from a slurry (with techniques described above) or spraying with granulating solution. Fig. 7 shows a top-spray granulator. An alternative method (Fig. 7) employs an auger to force the blend between rollers, thereby forming a compressed solid which disintegrates into large aggregates (48).

The steps involved in granulation begin with transferring powders to a mixer and blending the product. The granulation solution can be added and coarse milling or wet granulation begun. Finally, the product is dried and milled to an appropriate size.

Compression

Compressed solids, tablets, or caplets, are prepared by placing the blend of component additives in a cylinder or die, above a moveable piston or punch. An upper punch is brought into the top of the piston, and pressure applied to the distal ends of the punches forces the powder into a compact (Fig. 7). The quality of the product depends upon the cohesive forces acting on the powder upon compression. These cohesive forces are influenced by the selection of additives in the dosage formulation. One method of evaluating tablet manufacture considers the effect of the applied pressure on porosity of a compressed powder (49). Data may be plotted as the negative natural logarithm of porosity against applied pressure in the form of a Heckel plot (50). The slope of this plot is proportional to the yield value (ϕ , elastic limit) with a value of $1/3\phi$.

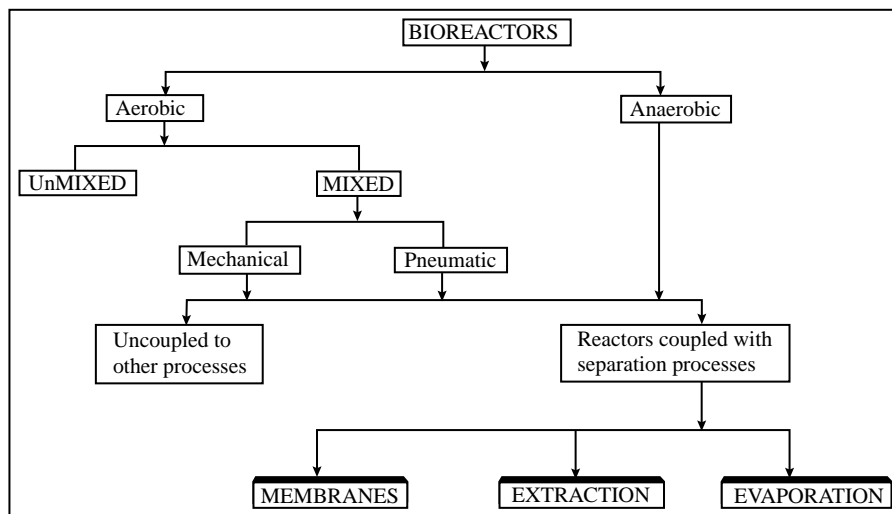

Fig. 8 Schematic of types of bioreactors.

Fig. 9 Bioreactors: (a) stirred tank reactor; (b) airlift fermentor.

Bioprocessing

The use of biotechnology in the manufacture of pharmaceuticals is of increasing interest. Consequently these techniques require attention in the planning of unit processes. Bioprocessing can be considered in terms of small-scale bioreactors, or fermenters, and the translation of such processes into large-scale economically viable production operations (51, 52).

Bioprocessing is by no means a new field. The topicality of this subject is due to the increased interest in the use of isolated cells and microorganisms as manufacturing tools. It might well be argued that this technology was developed millennia ago for the purposes of wine and beer production. More recently, the use of attenuated microorganisms or isolated antigenic materials for vaccination resulted in further developments. In the last decade, the interest in genetic engineering and manipulation of the genetic code of certain microorganisms has produced a revolution in the manufacturing of pharmaceuticals.

Bioreactors

The major difference between a biotechnological process and other pharmaceutical manufacturing operations is the need for a bioreactor (Fig. 8). These bioreactors may be required to produce expressed proteins utilizing bacteria, yeast, insect, or mammalian cells. It would be difficult to describe the various bioreactor elements and their

permutations. Some of the simplest examples of bioreactors are shown in Fig. 9.

CONCLUSION

Pharmaceutical manufacturing entails the combination of a number of unit processes. The major processes have been described in this article. Brief outlines of the applications of these processes to parenteral, solid dosage form, and biological materials production are given.

The efficiency, quality, and economy of manufacturing depends upon an understanding of the individual operations involved in processing. In many cases, unlike in other industrial processing, safety and efficacy of a therapeutic agent may be affected. A guide or introduction to the practical aspects of unit processes in pharmacy is provided here.

Vectora Ltd., Bath, United Kingdom

INTRODUCTION

Pharmaceutical manufacturing can be divided into a number of unit process on the basis of a few fundamental principles. The following monograph describes briefly fluid flow and heat and mass transfer.

FLUID FLOW

Fluids (liquids and gases) are a form of matter that cannot achieve equilibrium under an applied shear stress but deform continuously, or flow, as long as shear stress is applied.

Streamlines are hypothetical lines without width drawn parallel to all points to the motion of the fluid. As velocity increases, pressure decreases. Pressure field around an object is the reverse of velocity field. This may appear to contradict common experience. However, it follows from the principle of conservation of energy and finds expression in Bernoulli's theorem.

Bernoulli's Theorem

At any point in system through which a fluid is flowing, the total mechanical energy can be expressed in terms of potential energy, pressure energy, and kinetic energy.

Potential energy of a body is its capacity to do work by reason of its position relative to some center of attraction. For unit mass of fluid at a height z above some reference level, the potential energy is zg .

Pressure energy or flow energy is an energy form peculiar to the flow of fluids. The work done and the energy acquired in transferring the fluid is the product of the pressure P and the volume.

Volume of unit mass of the fluid is the reciprocal of the density ρ . For an incompressible fluid, the density is not dependent on the pressure, so for unit mass of fluid the pressure energy is P/ρ .

Kinetic energy is a form of energy possessed by a body by reason of its movement. If the mass of the body is m and

its velocity u , the kinetic energy is $1/2 mu^2$, and for unit mass of fluid the kinetic energy is $u^2/2$.

The total mechanical energy of unit mass of fluid is therefore

$$\frac{u^2}{2} + \frac{P}{\rho} + zg$$

and proved no energy is lost or gained by the system, the mechanical energy at two points A and B is the same as that expressed by Eq. 1.

$$\frac{u_A^2}{2} + \frac{P_A}{\rho} + z_A g = \frac{u_B^2}{2} + \frac{P_B}{\rho} + z_B g \quad (1)$$

This relationship neglects the frictional degradation of mechanical energy that occurs in real systems. A fraction of the total energy is dissipated in overcoming shear stresses induced by velocity gradients in the fluid. Energy E lost during flow between A and B must be considered. The dimensions of each component are $L^2 T^{-2}$, Length²Time⁻². In practice, each term is divided by g (LT^{-2}) to give the dimension of length. The terms are then referred to as velocity head, pressure head, potential head, and friction head, the sum giving the total head of the fluid as shown in Eq. 2.

$$\frac{u_A^2}{2g} + \frac{P_A}{\rho g + z_A} = \frac{u_B^2}{2g} + \frac{P_B}{\rho g} + z_B + \frac{E}{g} \quad (2)$$

The evaluation of the kinetic energy term requires consideration of the variation in velocity found in the direction normal to flow. The kinetic energy, given by the term $u_{\text{mean}}^2/2$, differs from the true kinetic energy found by summation across the flow direction. The former can be retained, however, if a correction factor a is introduced. Then

$$\text{velocity head} = \frac{u_{\text{mean}}^2}{2ga},$$

where a has a value of 0.5 in laminar flow and approaches unity in fully turbulent flow. Mechanical energy is added to the system at some point by means of a pump. The work W done, in absolute units, on a unit mass of fluid at A is given by Eq. 3.

$$\frac{W}{g} + \frac{u_A^2}{2g} + \frac{P_A}{\rho g} + z_A = \frac{u_B^2}{2g} + \frac{P_B}{\rho g + z_B} + \frac{E}{g} \quad (3)$$

The power required through a system at a certain rate may be calculated using Eq. 3 to drive a liquid. The sum of heads, ΔH , being the total head against which the pump must work is therefore

$$\frac{W}{g} + H$$

If the work performed and energy acquired by unit mass of fluid is ΔHg , the power required to transfer mass m in time t is given by

$$\text{Power} = \frac{Hgm}{t}$$

As the volume flowing in unit time Q is $m/\rho t$, the power is given by Eq. 4.

$$\text{Power} = QHg\rho \quad (4)$$

Flow Measurement

The Bernoulli theorem can also be applied to the measurement of flow rate. The passage of an incompressible fluid through a constriction results in an increase in velocity from u_1 to u_2 , which is associated with a decrease in pressure from P_1 to P_2 , which can be measured directly. The volumetric flow rate $Q = u_1 a_1 = u_2 a_2$ by algebraic rearrangement (which is not shown). The final linear velocity u_2 can be described by Eq. 5.

$$\frac{u_2^2}{2} - \frac{u_1^2}{2} = \frac{P_1 - P_2}{\rho} \quad (5)$$

The volumetric flow rate can be described by Eq. 6.

$$Q = a_2 \sqrt{\frac{2(P_1 - P_2)}{\rho(1 - a_2^2/a_1^2)}} \quad (6)$$

This derivation neglects the correction of kinetic energy loss due to nonuniformity of flow in both cross sections and the frictional degradation of energy during passage through the constriction. This is corrected by the introduction of a numerical coefficient, C_D , known as the coefficient of discharge, as shown in Eq. 6.

$$Q = C_D a_2 \sqrt{\frac{2(P_1 - P_2)}{\rho(1 - a_2^2/a_1^2)}}$$

The value of C_D depends on conditions of flow and shape of the constriction. For a well-shaped constriction (notably circular cross section), it would vary between 0.95 and 0.99 for turbulent flow. The value is much lower in laminar flow because the kinetic energy correction is larger. The return of the fluid to the original velocity by means of a diverging section forms a flow-measuring device known as a Venturi meter.

The Venturi meter is shown in Fig. 1(a). The converging cone leads to the narrowest cross section known as the throat. The change in pressure is measured across this part of the meter and the volumetric flow rate found by substitution into Eq. 6. Values of the coefficient of discharge are given previously. The diverging section or diffuser is designed to induce a gradual return to the original velocity. This minimizes eddy formation in the diffuser and permits the recovery of a large proportion of the increased kinetic energy as pressure energy. The permanent loss of head due to friction in both converging and diverging sections is small. The meter is therefore efficient.

When the minimization of energy degradation is less important, the gradual economic return to the original velocity may be abandoned, compensation for loss of efficiency being found in a device that is simpler, cheaper, and more adaptable than the Venturi meter. The orifice meter, to which this statement applies, consists simply of a plate with an orifice. A representation of flow through the meter is depicted in Fig. 1(b), indicating convergence of the fluid stream after passage through the orifice to give across section of minimum area called the *vena contracta*. The downstream pressure tapping is made at this cross section. The volumetric flow rate is given by Eq. 6 in which a_2 is the jet area at the *vena contracta*. The measurement of this dimension is inconvenient. It is therefore related to the area of the orifice, a_0 , which can be accurately measured by the coefficient of contraction C_c by the relation $C_c = a_2/a_0$.

The coefficient of contraction, frictional losses between the tapping points, and kinetic energy corrections are absorbed in the coefficient of discharge. The volumetric flow rate is then given by Eq. 7.

$$Q = C_D a_0 \sqrt{\frac{2(P_1 - P_2)}{\rho(1 - a_0^2/a_1^2)}} \quad (7)$$

If the orifice is small compared with the pipe cross section, the term $(1 - (a_0^2/a_1^2))$ approaches unity. As $P_1 - P_2 = \Delta h \rho g$, Δh being the difference in head developed by the orifice, Eq. 7 reduces to Eq. 8.

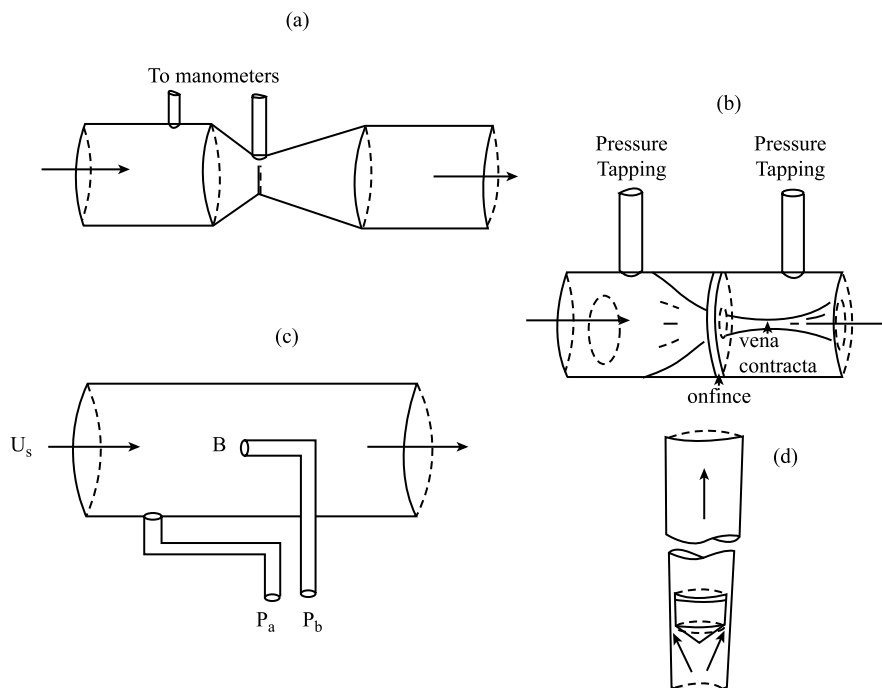

Fig. 1 (a) Venturi meter; (b) orifice meter; (c) Pitot tube; (d) rotameter.

$$Q = C_D a_0 (h \rho g)^{1/2} \quad (8)$$

The value of C_D for the orifice meter is about 0.6, varying with construction, the ratio a_0/a_1 , and flow conditions within the meter. Due to its complexity, it cannot be calculated.

After passage through the orifice, flow disturbance during retardation causes the dissipation of most of the excess kinetic energy as heat. The permanent loss of head is therefore high, increasing as the ratio of a_0/a_1 falls, ultimately reaching the differential head produced within the meter.

The Bernoulli theorem may be used to determine the change in pressure caused by retardation of fluid at the upstream side of a body immersed in a fluid stream. This principle is applied in the Pitot tube, shown in Fig. 1(c). The fluid velocity is reduced from u_a , the velocity of the fluid filament in alignment with the tube, to zero at B, an position known as the stagnation point. The pressure, P_b , is measured at this point by the method shown in Fig. 1(c). The undisturbed pressure, P_a , is measured in this example with a tapping point in the wall connected to a manometer. As the velocity at B is zero, Eq. 10 reduces to

$$\frac{u_a^2}{2} = \frac{p_b - P_a}{\rho}$$

and u_2 can be calculated. As only a local velocity is measured, variation of velocity in a section can be studied by altering the position of the tube. This procedure must be used if the flow rate in a pipe is to be measured. The mean velocity is derived from velocities measured at different distances from the wall. This derivation and the low pressure differential developed render the Pitot tube less accurate than either the venturi tube or the orifice meter for flow measurement. Hence, the tube is small in comparison with the pipe diameter and, therefore, produces no appreciable loss of head.

The rotameter (a variable area meter), shown in Fig. 1(d), is commonly used, giving a direct flow rate reading by the position of a small float in a vertical, calibrated glass tube through which the fluid is flowing. The tube is internally tapered toward the lower end so that the annulus between float and wall varies with the position of the float. Acceleration of the fluid through the annulus produces a pressure differential across the position of the float and an upward force upon it. At the equilibrium position, which may be stabilized by a slow rotation of the float, this upward force is balanced by the weight force acting on the float. If the equilibrium is disturbed by increasing the flow rate, the balance of weight force and the pressure differential are produced by movement of the float upward to a position at which the area of the annulus is bigger. For accurate measurement, the rotameter is

calibrated with the fluid to be metered. Its use is, however, restricted to that fluid.

Laminar and Turbulent Flow

The nature of flow may be examined by introducing a dye into the axis of the tube. At low speeds, the dye forms a coherent thread, which grows very little in thickness with distance down the tube. However, with progressive increase in speed, the line of dye begin to waver and then break up. Secondary motions crossing and recrossing the general flow direction occur. Finally, at very high speeds, no filament of dye is detected and mixing is instantaneous. In this experiment, flow changes from laminar to turbulent, the change occurring at a critical speed. Generalizing, in laminar flow, the instantaneous velocity at a point is always the same as the mean velocity in both magnitude and direction. In turbulent flow, order is lost and irregular motions are imposed upon the main steady motion of the fluid. At any instant of time, the fluid velocity at a point varies in both magnitude and direction, having components perpendicular as well as parallel to the direction of net flow. Over a period of time, these fluctuations even out to give the net velocity in the direction of flow.

In turbulent flow, rapidly fluctuating velocities produce high velocity gradients within the fluid. Proportionately large shear stresses are developed, and to overcome them, mechanical energy is degraded and dissipated in the form of heat. The degradation of energy in laminar flow is much smaller.

The turbulent mechanism that carries motion, heat, or matter from one part of the fluid to another is absent in laminar flow. The agency of momentum transfer is the shear stress arising from the variations in velocity, that is, the viscosity. Similarly, heat and matter can only be transferred across streamlines on a molecular scale, heat by conduction and matter by diffusion. These mechanisms that are present but less important in turbulent flow are comparatively slow. Velocity, temperature, and concentration gradients are, therefore, much higher than in turbulent flow.

The Flow of Liquids in Pipes

The many pharmaceutical processes that involve the transfer of a liquid confer great importance on the study of flow in pipes. This study permits the evaluation of pressure loss due to friction in a simple pipe and assesses the additional effects of pipe roughness, changes in diameter, bends, exits, and entrances. When the total pressure drop due to friction is known for the system, the equivalent head

can be derived and the power requirement for driving a liquid through the system can be calculated from Eq. 9.

Streamline flow in a tube

The mathematical analysis of streamline flow in a simple tube results in the expression known as Poiseuille's law, one form of which is Eq. 9.

$$Q = \frac{P\pi d^4}{128\eta l} \quad (9)$$

where Q is the volumetric flow rate or discharge, ΔP is the pressure drop across the tube, d and l are the diameter and length of the tube, respectively, and η is the viscosity of the fluid.

Where flow in the tube is streamline or turbulent, an infinitesimally thin stationary layer is found at the wall. The velocity increases from zero at this point to a maximum at the axis of the tube. The velocity profile of streamline flow is shown in Fig. 9(a). The velocity gradient du/dr varies from a maximum at the wall to zero at the axis. In flow through a tube, the rate of shear is equal to the velocity gradient, and Eq. 1 dictates the same variation of shear stress.

To derive Poiseuille's law, the form of the velocity profile must first be established. For a fluid contained within a radius r flowing in a tube of radius R , the pressure drop across length l is ΔP ; therefore, the pressure force driving this section is $\Delta P\pi r^2$. If the flow is steady, this force can only be balanced by opposing viscous forces acting on the "wall" of the section. This force is

$$\tau = \frac{Pr}{2l}$$

Substituting for Eq. 1 gives

$$-\frac{du}{dr} = \frac{Pr}{2\eta l}$$

The velocity gradient is negative because u decreases as r increases. If $r = R$, then $u = 0$. Integration gives

$$\int_0^u du = \frac{P}{2\eta l} \int_R^r r dr$$

Therefore, Eq. 10 can be written as

$$u = \frac{P}{2\eta l} \left(\frac{R^2 - r^2}{2} \right) \quad (10)$$

This relation shows that the velocity distribution across the tube is parabolic. For such a distribution, the maximum velocity is twice the mean velocity.

The volumetric flow rate across an annular section between r and $(r + dr)$ is given by

$$Q = 2\pi r dr u.$$

Substituting for u for Eq. 10 gives

$$Q = \frac{P\pi}{2\eta l} (R^2 r - r^3) dr$$

The total volumetric flow rate is the integral between the limits $r = R$ and $r = 0$:

$$Q = \frac{P\pi}{2\eta l} \int_0^R (R^2 r - r^3) dr = \frac{P\pi}{2\eta l} R^2 \left(\frac{r^2}{2} - \frac{r^4}{4} \right)_0^R$$

Therefore Eq. 9 is valid:

$$Q = \frac{P\pi R^4}{8\eta l} = \frac{P\pi d^4}{128\eta l}$$

where d is the diameter of the tube.

As $Q = u_{\text{mean}} \pi (d^2/4)$, substitution and rearrangement gives Eq. 11.

$$P = \frac{32u_{\text{mean}}\eta l}{d^2} \quad (11)$$

The Significance of Reynolds Number Re

The Reynolds number describes the ratio of the inertia and viscous or frictional forces. Higher the Reynolds number, greater is the relative contribution of inertial effects. At very low Re , viscous effects predominate and the contribution of inertial forces can be ignored.

Calculation of the Pressure Drop in a Pipe Due to Friction

If the volumetric flow rate of a liquid of density ρ and viscosity η through a pipe of diameter d is Q , the derivation of the mean velocity u from the flow rate and pipe area completes the data required for calculating Re . If the pipe roughness factor is known, the equivalent value of $R/\rho u^2$ can be read from Fig. 2, and the shear stress at the pipe wall calculated. The total frictional force opposing motion is the product of R and the surface area of the pipe, πdl , where l is the length of the pipe. If the unknown pressure drop across the pipe is ΔP , the force driving through the pipe is $\Delta P \cdot \pi d^2/4$. Equating pressure force and frictional force,

$$P = \frac{\pi d^2}{4} = R\pi dl$$

Fig. 2 Pipe friction chart $R/\rho u^2$ versus Re .

Therefore, Eq. 12 follows.

$$P = \frac{4Rl^2}{d} \quad (12)$$

Division by ρg gives the pressure loss as a friction head.

Flow in Tubes of Noncircular Cross Section

The foregoing arguments may be applied to turbulent flow in noncircular ducts by introducing a dimension equivalent to the diameter of a circular pipe. This is known as the mean hydraulic diameter, d_m , which is defined as four times the cross-sectional area divided by the wetted perimeter. The following examples are given:

For a square channel of side b ,

$$d_m = \frac{4b^2}{4b} = b.$$

For an annulus of outer radius r_1 and inner radius r_2 ,

$$\frac{4(\pi r_1^2 - \pi r_2^2)}{2\pi r_1 + 2\pi r_2} = 2(r_1 - r_2)$$

This simple modification does not apply to laminar flow in noncircular ducts.

Frictional Losses at Pipe Fittings

In addition to the friction losses at the wall of a straight pipe, losses occur at the various fittings and valves used in practical systems. In general, these losses are derived from sudden changes in the magnitude or direction of flow induced by changes in geometry. They can be classified as losses due to a sudden contraction or enlargement, losses at entrance or exit, and losses due to pipe curvature. Losses can be conveniently expressed as a length of straight pipe offering the same resistance. This is usually in the form of a number of pipe diameters. For

example, the loss at a right-angled elbow is equivalent to the length of a straight pipe equal to 40 diameters. The sum of the equivalent lengths of all fittings and vales is then added to the actual pipe length and the total frictional loss estimated by Eq. 20.

Motion of Bodies in a Fluid

Viscous and inertial forces operate to determine the flow pattern and drag force on a body moving relative to a fluid. The Reynolds number, which expresses their ratio, is used as a parameter to predict flow behavior. The relation between the drag force and its controlling variables is presented in a manner similar to that employed for flow in a pipe. Considering a sphere moving relative to a fluid, the projected area normal to flow is $\pi d^2/4$, where d is the diameter of the sphere. The drag force acting on the unit projected area R' is determined by the velocity u , the viscosity η , and the density ρ of the fluid and the diameter of the sphere d . Dimensional analysis yields Eq. 13.

$$\frac{R}{\rho u^2} = f(Re) = f\left(\frac{ud\rho}{\eta}\right) \quad (13)$$

This form of Reynolds number, Re' , employs the diameter of the sphere as the linear dimensions.

With the exception of an analysis at very low Re values, the form of this function is established by experiment. Results are presented on logarithmic coordinates in Fig. 3. When Re' is less than about 0.2,

Fig. 3 $R'/\rho u^2$ versus Re' number for a smooth sphere.

viscous forces are solely responsible for drag on the sphere and Eq. 13 becomes

$$\frac{R}{\rho u^2} = \frac{12}{Re}$$

Therefore,

$$\text{Total drag force} = R \frac{\pi d^2}{4} = \rho u^2 \frac{12 \pi d^2}{Re \cdot 4} = 3\pi\eta du \quad (14)$$

This is the normal form of Stokes law.

At larger Re' values, the experimental curve progressively diverges from this relation, ultimately becoming independent of Re' and giving a value of $R/\rho u^2$ equal to about 0.22. As Re' increases, the form drag increases, ultimately becoming solely responsible for the force opposing motion.

For nonspherical particles, the analysis employs the diameter of a sphere of equivalent volume. A correction factor, which depends upon the shape of the body and its orientation in the fluid, must be applied.

An important application of this analysis is the estimation of the speed at which particles settle in a fluid. Under the action of gravity, the particle accelerates until the weight force mg is exactly balanced by the opposing drag. The body then falls at a constant terminal velocity u . Equating weight and drag forces gives Eq. 15.

$$mg = \frac{\pi}{6} d^3 (\rho_s - \rho) g = R \frac{\pi d^2}{4} \quad (15)$$

where ρ is the density of the particle.

For a sphere falling under streamline conditions ($Re' < 0.2$), $R' = \rho u^2 (12/Re')$. Substituting in Eq. 15 gives Eq. 16.

$$u = \frac{d^2 (\rho_s - \rho) g}{18\eta} \quad (16)$$

This expression follows more simply from the equation $mg = 3\pi d\eta u$.

Flow of Fluids Through Packed Beds

The analysis of the flow of fluids through a permeable bed of solids is widely applied in filtration, leaching, and several other processes. A first approach may be made by assuming that the interstices of the bed correspond to a large number of discrete, parallel capillaries. If the flow is streamline, the volumetric flow rate Q is given for a single capillary by Eq. 14:

$$Q = \frac{P\pi d^4}{128\eta l}$$

where l is the length of the capillary and d its diameter, ΔP is the pressure drop across the capillary, and η is the viscosity of the fluid. The length of the capillary exceeds the depth of the bed by a value that depends upon its tortuosity. The depth of bed, L , is however, proportional to the capillary length l so that

$$Q = \frac{Pd^4}{k\eta L},$$

where k is a constant for a particular bed. If the area of the bed is A and it contains n capillaries per unit area, the total flow rate is given by

$$Q = \frac{Pd^4 nA}{k\eta L}$$

Both n and d are not normally known. However, they have certain values for a given bed, expressed by Eq. 17.

$$Q = KA \frac{P}{\eta L} \quad (17)$$

where $K = d^4 n/k$. This constant is a permeability coefficient and its reciprocal, $1/K$, is the specific resistance. Its value characterizes a particular bed.

The postulate of discrete capillaries precludes valid comment on the factors that determine the permeability coefficient. Channels are not discrete but are interconnected in a random manner. Nevertheless, the resistance to the passage of fluid must depend on the number and dimensions of the channels. These can be expressed in terms of the fraction of the bed which is void, that is, the porosity, and the manner in which the void fraction is distributed. Illustrating this reference to a specific example, water would flow more easily through a bed with a porosity of 40% than through a bed of the same material with a porosity of 25%. It would also flow more quickly through a bed of coarse particles than through a bed of fine particles packed to the void fraction or porosity. The latter effect can be expressed in terms of the surface area offered to the fluid by the bed. This property is inversely proportional to the size of the particles forming the bed. Permeability increases as the porosity increases and the total surface of the bed decreases and these factors may be combined to give the hydraulic diameter d' of an equivalent channel. This is defined by:

$$d = \frac{\text{Volume of voids}}{\text{Total surface of material forming bed}}$$

The volume of voids is the porosity, and the volume of solids is $(1 - \varepsilon)$. If the specific surface area, that is, the surface area of unit volume of solids, is S_0 , the total surface presented by unit volume of the bed is $S_0(1 - \varepsilon)$.

Therefore, Eq. 18 applies.

$$d = \frac{\varepsilon}{S_0(1 - \varepsilon)} \quad (18)$$

Under streamline conditions, the rate at which a fluid flows through this equivalent channel is given by Poiseuille's Eq. 14.

The velocity u' in the channel is derived by dividing the volumetric flow rate by the area of the channel, $k'd'^2$. Combining the constants,

$$u = \frac{Q}{kd^2} = \frac{Pd^2}{k\eta L}$$

This velocity, when averaged over the entire area of the bed, solids, and voids, gives the lower value u . These velocities are related by

$$u = u\varepsilon$$

Therefore:

$$\frac{u}{\varepsilon} = \frac{Pd^2}{k\eta L}$$

Substituting for d' by means of Eq. 18 gives

$$\frac{u}{\varepsilon} = \frac{P}{k\eta L} \frac{\varepsilon^2}{(1 - \varepsilon)^2 S_0^2}$$

and Eq. 19.

$$u = \frac{P}{k\eta L} \frac{\varepsilon^3}{(1 - \varepsilon)^2 S_0^2} \quad (19)$$

In this equation, known after its originator as Kozeny's equation, the constant k'' has a value of 5 ± 0.5 . As $Q = uA$, where A is the area of the bed, Eq. 19 can be transformed to Eq. 20.

$$Q = \frac{PA}{\eta L} \cdot \frac{\varepsilon^3}{5(1 - \varepsilon)^2 S_0^2} \quad (20)$$

This analysis shows that permeability is a complex function of porosity and surface area, the latter being determined by the size distribution and shape of the particles. The appearance of specific surface in Eq. 20 offers a method for its measurement and provides the basis of fluid permeation methods of size analysis. This equation also applies in the studies of filtration.

Pumps

Eqs. 8 and 9 examine the power requirement for driving a liquid through a system against an opposing head. This energy is normally generated by a pump. In different

processes, the quantities to be delivered, the opposing head, and the nature of the fluid vary widely, and many pumps are made to meet these differing requirements. Basically, however, pumps can be divided into positive-displacement pumps, which may be reciprocating or rotary, and impeller pumps. Positive-displacement pumps seek to displace a fixed volume of fluid with each stroke or revolution; impeller pumps, on the other hand, impart high kinetic energy to the fluid which is subsequently converted to pressure energy. The volume discharged depends upon the opposing head.

The equipment for pumping gases and liquids is essentially similar. Machines delivering gases are commonly called compressors or blowers; compressors discharge at relatively high pressures and blowers at relatively low pressures. The lower density and viscosity of gases results in higher operating speeds and, to minimize leakage, smaller clearance between moving parts.

HEAT TRANSFER

Heat transfer in process vessels has been described previously in this encyclopedia (1). The following is a more complete review of heat transfer as a unit operation in pharmacy. Heat energy can only be transferred from a region of higher to a region of lower temperature. Understanding heat transfer requires the study of the mechanism and rate of this process.

Heat is transferred by three mechanisms: conduction, convection, and radiation. It is unusual for the transfer to take place by one mechanism only.

Conduction is the most widely understood mechanism of heat transfer and the main method in solids. The flow of heat depends upon the transfer of vibrational energy from one molecule to another and, in the case of metals, the movement of free electrons. Radiation is rare in solids but examples are found among glasses and plastics. Convection by definition, is not possible under these conditions. Conduction in the bulk of fluids is normally overshadowed by convection, but it assumes great importance at fluid boundaries.

Heat is transferred from or to a region by the motion of fluids and the phenomenon of convection. In natural convection, the movement is caused by buoyancy forces induced by variations in the density of the fluid; these variations are caused by differences in temperature. In forced convection, movement is created by an external agency such as a pump.

All bodies with a temperature above absolute zero radiate heat in the form of electromagnetic waves.

The radiation may be transmitted, reflected, or absorbed by matter, the fraction absorbed being transformed into heat. Radiation is of great importance at very high or very low temperatures and under circumstances in which the other modes of heat transmission are suppressed. Although the heat losses can, in some cases, equal the losses by natural convection, the mechanism is, from the standpoint of pharmaceutical processing, least important and needs only brief consideration.

Heat transfer in many systems occurs as a steady-state process, and the temperature at any point in the system does not vary with time. In other important processes, temperatures in the system do vary with time. This situation, which is common among the small-scale, batch-operated processes of the pharmaceutical and fine chemical industry, is known as unsteady heat transfer and, as warming or cooling occurs, the thermal capacity (i.e., the size and specific heat), of the system becomes important. Analysis of unsteady heat transfer is complex.

Heat Transfer Through a Wall

Heat transfer by conduction through walls follows the basic relation given by Fourier's equation (Eq. 21), which states that the rate of heat flow, Q , is proportional to the temperature gradient, dT/dx , and to the area normal to the heat flow, A .

$$Q = -kA \frac{dT}{dx} \quad (21)$$

As the distance x increases, the temperature T decreases. Hence, measuring in the x direction, the temperature gradient, dT/dx , is algebraically negative. The proportionality constant k is the thermal conductivity. Its numerical value depends on the material of which the body is made and on its temperature.

Metals exhibit high conductivity, although values vary widely. Nonmetallic solids normally have lower conductivities than do metals. For the porous materials of this group, the overall conductivity lies between that of the homogeneous solid and the air that permeates the structure. Low resultant values lead to wide use as heat insulators. Carbon is an exception among nonmetals. Its relatively high conductivity and chemical inertness permit its wide use in heat exchangers.

Steady nondirectional heat transfer through a plane wall of thickness x and area A is represented in Fig. 4(a). Assuming that thermal conductivity does not change with temperature, the temperature gradient is linear and equal to $(T_1 - T_2)/x$, where T_1 is the temperature of the hot face and

Fig. 4 Conduction of heat through (a) a plane wall and (b) a composite wall.

T_2 the temperature of the cool face. Eq. 21 then becomes Eq. 22

$$Q = kA \frac{T_1 - T_2}{x} \quad (22)$$

This may be rearranged to Eq. 23

$$Q = A \frac{T_1 - T_2}{x/k} \quad (23)$$

where x/k is the thermal resistance. Thus, for a given heat flow, a large temperature drop must be created if the wall or layer has a high thermal resistance.

Conversely, the heat flow promoted by a given temperature difference is reduced if the thermal resistance is increased. This is the principle of insulation by lagging, and it is illustrated by a composite wall, as shown in Fig. 4(b). If steady-state heat transfer exists, the rate of heat transfer is the same for both materials. Therefore,

$$Q = \frac{k_1 A (T_1 - T_2)}{x_1} = \frac{k_2 A (T_2 - T_3)}{x_2}$$

The major temperature drop occurs across the distance x_2 , indicating that this material provides the major thermal resistance. (In the case of heavily lagged, thin metal walls, the temperature drop and thermal resistance of the metal are so small that they can be ignored). Rearrangement of this equation and the elimination of the junction temperature gives Eq. 24.

$$Q = A \frac{(T_1 - T_3)}{(x_1/k_1 + x_2/k_2)} \quad (24)$$

Equations of this form can be applied to any number of layers.

Heat Transfer in Pipes and Tubes

Pipes and tubes are common as barriers over which heat exchange takes place. Conduction is complicated in this case by the changes in the area over which heat is transferred. If Eq. 21 is to be retained, some value of A must be derived from the length of the pipe, l , and the internal and external radii, r_1 and r_2 , respectively. If the pipe is thin-walled and the ratio r_2/r_1 is less than approximately 1.5, the heat transfer area can be based on an arithmetic mean of the two radii, and Eq. 21 becomes Eq. 25.

$$Q = k2\pi \frac{r_2 + r_1}{2} l \frac{T_1 - T_2}{r_2 - r_1} \quad (25)$$

This equation is inaccurate for thick-walled pipes, where the heat transfer area must be based on a logarithmic mean radius r_m . Heat transfer is then expressed by Eq. 26

$$Q = k2\pi r_m l \frac{T_1 - T_2}{r_2 - r_1} \quad (26)$$

where

$$r_m = \frac{r_2 - r_1}{\log_{e} \frac{r_2}{r_1}}$$

Heat Exchange Between a Fluid and a Solid Boundary

Conduction and convection contribute to the transfer of heat from a fluid to a boundary. The distribution of temperatures at a plane barrier separating two fluids may be considered. If the fluids are turbulent motion, temperature gradients are confined to a relatively narrow region adjacent to the wall. Outside this region, turbulent mixing, the mechanism of which has been explained earlier, is very effective in the transfer of heat. Temperature gradients are quickly destroyed and equalization at values T_1 and T_2 occurs. Within the region, there exists a laminar sublayer across which heat is transferred by conduction only. The temperature gradients produced by a given heat flow are correspondingly high. Outside the laminar layer, eddies contribute to the transfer of heat by moving fluid from the turbulent bulk to the edge of the sublayer, where heat can be lost or gained, and by corresponding movements in the opposite direction. The temperature gradients in this region, where both convection and conduction contribute to heat transfer, are smaller than in the sublayer.

The major resistance to the flow of heat resides in the laminar sublayer. Its thickness, therefore, is of critical importance in determining the rate of heat transfer from

the fluid to the boundary. It depends on the physical properties of the fluid, the flow conditions, and the nature of the surface. Increase in flow velocity, for example, decreases the thickness of the layer and, therefore, its resistance to heat flow.

To evaluate the rate of heat transfer at a boundary, a film, transmitting heat only by conduction is postulated. This fictitious film presents the same resistance to heat transfer as the complex turbulent and laminar regions near the wall. If on the hot side of the wall the fictitious layer had a thickness x_1 , the equation of heat transfer to the wall would be

$$Q = kA \frac{T_1 - T_{1\text{ wall}}}{x_1}$$

where k is the thermal conductivity of the fluid. A similar equation applies to heat transfer at the cold side of the wall. The thickness of the layer is determined by the same factors that control the extent of the laminar sublayer. In general the layer thickness is not known and the above equation is rewritten as Eq. 27.

$$Q = h_1 A (T_1 - T_{1\text{ wall}}) \quad (27)$$

where h_1 is the heat-transfer coefficient for the film under discussion. It corresponds to the ratio k/x_1 and is the $\text{Btu/ft}^2 \cdot \text{h} \cdot ^\circ\text{F}$. It is a convenient numerical expression of heat flow by conduction and convection at a boundary. The approximate evaluation of these coefficients is discussed later.

The film coefficient h_2 may be used to characterize heat transfer from the barrier to the colder fluid.

$$T_1 - T_{1\text{ wall}} = \frac{Q}{h_1 A} \quad T_{1\text{ wall}} - T_{2\text{ wall}} = \frac{Q x_w}{h_w A}$$

where k_w is the thermal conductivity of the wall, and

$$T_{2\text{ wall}} - T_2 = \frac{Q}{h_2 A}$$

Addition and rearrangement of these equations gives Eq. 28.

$$Q = \frac{A}{(1/h_1 + x_w/k_w + 1/h_2)} (T_1 - T_2) \quad (28)$$

The quantity

$$\frac{1}{(1/h_1 + x_w/k_w + 1/h_2)}$$

is called the overall heat-transfer coefficient U . A general expression of the rate of heat transfer then becomes Eq. 29.

$$Q = UAT \quad (29)$$

or

$$\frac{ql}{Tk} = \text{constant} \left(\frac{l^3 Tag \rho^2}{\eta^2} \right) \left(\frac{C_p \eta}{k} \right)^q \quad (30)$$

Heat transfer by free convection can thus be presented as a relation between three dimensionless groups: $C_p \eta / k$ is known as the Prandtl number, the combination $l^3 \Delta T a g \rho^2 / \eta^2$ as the Grashof number, and $ql / \Delta T$, the Nusselt number may also be written hl/k .

The specific relation in which these groups stand is established for a particular system experimentally.

The fluid properties, C_p , k , η , and ρ are themselves temperature dependent. In establishing a correlation, the temperature at which these properties are to be measured must be chosen. This is usually the temperature of the main body of the fluid or the mean of this temperature and the temperature of the surface.

The exponents r and q are usually found experimentally to be equal to 0.25 in streamline flow and 0.33 in turbulent flow. The constant varies with the configuration. As an example, the heat transfer to gases and liquids from a large horizontal pipe by free convection is described by Eq. 31.

$$\frac{qd}{kT} = 0.47 \left(\frac{d^3 Tag \rho^2}{\eta^2} \right) \left(\frac{C_p \eta}{k} \right)^{0.25} \quad (31)$$

The linear dimension in this correlation is the pipe diameter d . The fluid properties are to be measured at the mean of the wall and bulk fluid temperatures.

In forced convection, the fluid is moved over the surface by a pump or blower neglecting natural convection are usually neglected. The study of forced convection is of great practical importance and vast amount of data have been amassed for streamline and turbulent flow in pipes, across and parallel to tubes, across plane surfaces, and in other important configurations such as jackets and coils.

In forced convection, the heat transferred per unit area per unit time q , is determined by a linear dimension which characterizes the surface l , the temperature difference between the surface and the fluid, ΔT , the viscosity η , the density ρ , and the velocity u , of the fluid, its conductivity k , and its specific heat C_p . Dimensional analysis yields Eq. 32

$$\frac{qd}{kT} = \text{constant} \left(\frac{C_p \eta}{k} \right)^x \left(\frac{ul\rho}{\eta} \right)^y \quad (32)$$

where ql/kT is the Nusselt number, Nu , $C_p \eta / k$ is the Prandtl number, Pr , and $ul\rho / \eta$ is the Reynolds number, Re , a parameter discussed previously. The values of the indices, x and y and of the constant are established for a particular system experimentally. In the case of turbulent flow in

pipes, the correlation for fluids of low viscosity is given by Eq. 33.

$$Nu = 0.023 Pr^x Re^{0.8} \quad (33)$$

where x has the value 0.4 for heating and 0.3 for cooling. The linear dimension used to calculate Re or Nu is the pipe diameter, and the physical properties of the fluid are to be measured at the bulk fluid temperature. This relation shows that in a given system, the film coefficient varies as the fluid velocity^{0.8}. If the flow velocity is doubled, the film coefficient increases by a factor of 1.7.

Heat Transfer to Boiling Liquids

Heat transfer to boiling liquids occurs in a number of operations, for example, distillation and evaporation. Heat is transferred by both conduction and convection in a process further complicated by the phase change that occurs at the heating boundary. When boiling is induced by a heater in contact with a pool of liquid, the process is known as pool boiling. Liquid movement is derived only from heating effects. In other systems, the boiling liquid may be driven through or over heaters, a process referred to as boiling with forced circulation.

Pool boiling

If a horizontal heating surface is in contact with a boiling liquid, a sequence of events occurs as the temperature difference between the surface and the liquid increases.

When ΔT is small, the degree of superheating of the liquid layers adjacent to the surface is low and bubble formation (growth and disengagement), if present, is slow. Liquid disturbance is small and heat transfer can be estimated from expressions for natural convection given, for example, in Eq. 29.

Vapor formation becomes more vigorous and bubble chains rise from points that progressively increase in number and finally merge. This movement increases liquid circulation. This phase is called nucleate boiling and is the practically important regime. A peak flux occurs and a maximum heat-transfer coefficient is obtained. At this point, ΔT is known as the critical temperature drop. For water, the value lies between 40 and 50°F (4–10°C). The critical temperature drop for organic liquids is somewhat higher. Beyond the critical temperature, vapor formation is so rapid that escape is inadequate and a progressively larger fraction of the heating surface becomes covered with a vapor film. This represents a transition from nucleate boiling to film boiling. When this transition is complete, the vapor entirely covers the surface, film boiling is fully established, and the heat flux rises again.

The low heat-transfer coefficient renders film boiling undesirable and equipment is designed for and operated at temperature differences which are less than the critical temperature drop. If a constant temperature heat source such as steam or hot liquid is employed, exceeding the critical temperature drop results simply in a drop in heat flux and process efficiency. If, however, a constant heat-input source is used, as in electrical heating, decreasing heat flux as the transition region is entered causes a sudden and possibly damaging increase in the temperature of the heating element; such damage is known as boiling burn-out.

Boiling heat-transfer coefficients depend upon both the physical character of the liquid and the nature of the heating surface. Through the agencies of wetting, roughness, and contamination, the latter greatly influences the formation, growth, and disengagement of bubbles in the nucleate boiling regime. There is, at present, no reliable method of estimating the boiling coefficients of heat transfer from the physical properties of the system.

Boiling inside a vertical tube

Heat transfer to liquids boiling in vertical tubes is common in evaporators. If a long tube of suitable diameter in which liquid lies at a low level is heated, the pattern of boiling is established Fig. 5. At low levels, boiling may be suppressed by the imposed head [Fig. 5(a)]. Higher in the tube, bubbles are produced, which rise and coalesce [Fig. 5(b)]. Slug formation due to bubble coagulation occurs [Fig. 5(c) and 5(d)]. The slugs finally break down [Fig. 5(e)]. Escape is hindered and both liquid and vapor move upward at an increasing speed. Draining leads to separation of the phases, giving an annular film of liquid dragged upward by a core of high velocity vapor [Fig. 5(f)]. In long tubes, the main heat transfer takes place in this region by either forced convection or nucleate boiling. At low temperature differences between wall and film, heat transfer occurs quietly as in forced convection. This is the normal regime in a climbing film evaporator and heat flux can be calculated from correlations of the type given in Eq. 40. At high temperatures differences, nucleate boiling takes place in the film and the vigorous movement leads to an increase in heat transfer coefficient.

Boiling with forced circulation

In many systems, movements other than those caused by boiling are imposed. For example, boiling in agitated vessels is common in many batch processes. The boiling heat-transfer coefficients depend upon the properties of the liquid, the nature of the surface, and the agitation. The coefficients obtained are slightly higher than those of pool boiling. Inside the tubes, the pattern of forced circulation

Fig. 5 Boiling in a narrow vertical tube. (a) Boiling suppressed by head, natural convection is shown; (b) bubble formation; (c) slug formation due to bubble coagulation; (d) fully developed slug flow; (e) breakdown of slugs at high vapor rates; (f) annular-flow-climbing film.

boiling is similar to that described in the previous section. Coefficients, however, are higher because the velocities attained are higher.

Heat Transfer from Condensing Vapors

When a saturated vapor is brought into contact with a cool surface, heat is transferred to the surface and a liquid condenses. The vapor may consist of a single substance or a mixture, some components of which may be non-condensable.

The process is described by the following sequence. The vapor diffuses to the boundary where actual condensation takes place. In most cases, the condensate

forms a continuous layer over the cooling surface, draining under the influence of gravity. This is known as film condensation. The latent heat liberated is transferred through the film to the surface by conduction. Although this film offers considerable resistance to heat flow, film coefficients are usually high.

Dropwise condensation

Under some surface conditions, the condensate does not form a continuous film. Droplets are formed which grow, coalesce, and then run from the surface. As a fraction of the surface is always directly exposed to the vapor, film resistance is absent, and heat-transfer coefficients, which may be ten times those of film condensation, are obtained. This process is known as dropwise condensation. Although highly desirable, its occurrence, which depends upon the wettability of the surface, is not predictable and cannot be used as a basis for design.

Condensation of a pure vapor

For film condensation, a theoretical analysis of the laminar flow of a liquid film down an inclined surface and the progressive increase in thickness due to condensation yields Eq. 34 for the mean-transfer coefficient h_m

$$h_m = \text{constant} \left(\frac{\rho^2 k^3 \lambda g}{T \eta x} \right)^{0.25} \quad (34)$$

where λ is the latent heat of vaporization; ρ , k , and η are the density, thermal conductivity, and viscosity of the liquid, respectively; ΔT is the difference in temperature between the surface and vapor. Experimentally determined coefficients confirm the validity of Eq. 34. In practice, however, the coefficients are somewhat higher due to disturbance of the film arising from a number of actors. As the condensation rate rises, the thickness of the condensate layer increases and the film coefficient falls. However, a point may be reached in long vertical tubes at which flow in the layer becomes turbulent. Under these conditions, the coefficient rises again and Eq. 34 is not valid. Coefficients may also be increased if high vapor velocities induce ripples in the film.

Condensation of mixed vapors

If a mixture of condensable and noncondensable gases is cooled below its dew point at a surface, the former condenses, leaving the adjacent layers richer in the latter, thus creating an added thermal resistance. The condensable fraction must diffuse through this layer to reach the film of condensate and heat-transfer coefficients are normally very much lower than the corresponding value for the pure vapor. For example, the presence of 0.5% of

air has been found to reduce the heat transfer by condensation of steam by as much as 50%.

Heat Transfer by Radiation

Of the radiation that falls on a body, a fraction a is absorbed, a fraction r is reflected, and a fraction t is transmitted. These fractions are called absorptivity, reflectivity, and transitivity, respectively. Most industrial solids are opaque such that the transmissivity is zero and Eq. 35 holds.

$$a + r = 1 \quad (35)$$

Reflectivity, and therefore, absorptivity depend greatly on the nature of the surface. The limiting case, that of a body which absorbs all and reflects none of the incident radiation, is called a black body.

Exchange of radiation

The exchange of radiation is based upon two laws. The first, known as Kirchoff's law, states that the ratio of the emissive power to the absorptivity is same for all bodies in thermal equilibrium. The emissive power of a body, E , is the radiant energy emitted from unit area in unit time. A body of area A_1 and emissivity E_1 , therefore, emits energy at a rate $E_1 A_1$. If the radiation falling on unit area of the body is E_b , the rate of energy absorption is $E_b a_1 A_1$, where a_1 is the absorptivity. At thermal equilibrium, $E_b a_1 A_1 = E_1 A_1$. For another body in the same environment, $E_b a_2 A_2 = E_2 A_2$, leading to Eq. 36

$$E_b = \frac{E_1}{a_1} = \frac{E_2}{a_2} \quad (36)$$

For a black body, $a = 1$. The emissive power is therefore E_b . The black body is a perfect radiator and is used as the comparative standard for other surfaces. The emissivity e of a surface is defined as the ratio of the emissive power E of the surface to the emissive power of a black body at the same temperature E_b , as shown by Eq. 37.

$$e = \frac{E}{E_b} \quad (37)$$

Emissivity is numerically equal to absorptivity. As emissive power varies with wavelength, the ratio should be quoted at a particular wavelength for many materials. However, the emissive power is a constant fraction of the black body radiation, that is, the emissivity is constant. These materials are known as gray bodies.

The second fundamental law of radiation, known as the Stefan-Boltzmann law, states that the rate of energy

emission from a black body is proportional to the fourth power of the absolute temperature T , as shown by Eq. 38

$$E = \sigma T^4 \quad (38)$$

where E is the total emissive power and σ is the Stefan-Boltzmann constant. It is sufficiently accurate to say that the heat emitted in unit time Q from a black body of area A is given by

$$Q = \sigma A T^4$$

and for a body that is not perfectly black by Eq. 39

$$Q = \sigma e A T^4 \quad (39)$$

where e is the emissivity.

The net energy gained or lost by a body can be estimated by these laws. The simplest case is that of a gray body in black surroundings. These conditions, in which none of the energy emitted by the body is reflected back, are approximately those of a body radiating to atmosphere. If the absolute temperature of the body is T_1 , the rate of heat loss is $\sigma e A T_1^4$ (Eq. 40), where A is the area of the body and e its emissivity. Surroundings at a temperature T_2 emit radiation proportional to σT_2^4 , and a fraction, determined by area and absorptivity a , is absorbed by the body; this heat is $\sigma a A T_2^4$, and as absorptivity and emissivity are equal, Eq. 40 is valid.

$$\text{Net heat-transfer rate} = \sigma e A (T_1^4 - T_2^4) \quad (40)$$

If part of the energy emitted by a surface is reflected back by another surface, the calculation of radiation exchange is more complex. Equations for various surface configurations take the following general form:

$$Q = F_1 F_2 \sigma A (T_A^4 - T_B^4)$$

where F_1 and F_2 are factors determined by the configuration and emissivity of surfaces at temperatures T_A and T_B .

MASS TRANSFER

Mass transfer in unit operations has been described in detail previously in this encyclopedia (2). the following is a brief review to complete the overview of unit processes in pharmacy.

In mass transfer operations, two immiscible phases are normally present, one or both of which are fluid. In general, these phases are in relative movement and the rate at which a component is transferred from one phase to the other is greatly influenced by the bulk movement imposed

upon the fluids. In most drying processes, for example, water vapor diffuses from a saturated layer in contact with the drying surface into a turbulent air stream. The boundary layer, as described earlier, consists of a sublayer in which flow is laminar and an outer region in which flow is turbulent. The mechanism of diffusion differs in these regimes. In the laminar layer, movement of water vapor molecules across streamlines can occur only by molecular diffusion. In the turbulent region, the movement of relatively large units of gas, called eddies, from one region to another causes mixing of the components of the gas. This is called eddy diffusion. Eddy diffusion is a more rapid process and although molecular diffusion is still present, its contribution to the overall movement of material is small. In still air, eddy diffusion is virtually absent and evaporation occurs by molecular diffusion.

Molecular Diffusion of Gases

Transport of material in stagnant fluids or across streamlines of a fluid in laminar flow occurs by molecular diffusion. Two adjacent compartments, separated by a partition containing pure gases A or B may be envisaged. Random movement of all molecules occurs so that after a period of time, molecules are found quite remote from their original positions. If the partition is removed, some molecules of A move toward the region occupied by B, their number depending on the number of molecules at the point considered. Concurrently, molecules of B diffuse toward regions formerly occupied by pure A.

Ultimately, complete mixing occurs. Before this point in time, a gradual variation in the concentration of A occurs along an axis, designated x , which joins the original compartments. This variation, expressed mathematically, is $-dC_A/dx$, where C_A is the concentration of A. The negative sign arises because the concentration of A decreases as the distance x increases. Similarly, the variation in the concentration of gas B is $-dC_B/dx$. The rate of diffusion of A, N_A , depends on the concentration gradient and the average velocity with which the molecules of A move in the x direction. This relationship is expressed by Fick's law, given by Eq. 41

$$N_A = -D_{AB} \frac{dC_A}{dx} \quad (41)$$

where D is the diffusivity of A in B, a property proportional to the average molecular velocity and, therefore, dependent on the temperature and pressure of the gases. The rate of diffusion N_A is usually expressed as the number of moles diffusing across unit area in unit time. As

with the basic equations of heat transfer, Eq. 41 indicates that the rate of a process is directly proportional to a driving force, which, in this context, is a concentration gradient.

This basic equation can be applied to a number of situations. Restricting discussion exclusively to steady-state conditions, in which neither dC_A/dx or dC_B/dx change with time, equimolecular counterdiffusion is considered first.

Equimolecular counterdiffusion

If no bulk flow occurs in an element of length dx , the rates of diffusion of the two gases A and B must be equal and opposite, that is, $N_A = -N_B$.

The partial pressure of A changes by dP_A over the distance dx . Similarly, the partial pressure of B changes dP_B . As there is no difference in total pressure across the element (no bulk flow), dP_A/dx must equal $-dP_B/dx$. For an ideal gas, the partial pressure is related to the molar concentration by the relation

$$P_A V = n_A RT$$

where n_A is the number of moles of gas A in a volume V . As the molar concentration C_A is equal to n_A/V , therefore

$$P_A = C_A RT$$

Consequently, for gas A, Eq. 40 can be written as in Eq. 42,

$$N_A = -\frac{D_{AB}}{RT} \frac{dP_A}{dx} \quad (42)$$

where D_{AB} is the diffusivity of A in B. Similarly,

$$N_B = -\frac{D_{BA}}{RT} \frac{dP_B}{dx} = \frac{D_{AB}}{RT} \frac{dP_A}{dx}$$

It, therefore, allows that $D_{AB} = D_{BA} = D$. If the partial pressure of A at x_1 is P_{A1} and at x_2 is P_{A2} , integration of Eq. 42 gives Eq. 43.

$$N_A = -\frac{D}{RT} \left(\frac{P_{A2} - P_{A1}}{x_2 - x_1} \right) \quad (43)$$

A similar equation may be derived for the counterdiffusion of gas B.

Diffusion through a stationary, nondiffusing gas

An important practical case arises when a gas A diffuses through a gas B, there being no overall transport of gas B. It arises, for example, when a vapor formed at a drying surface diffuses into a surrounding gas. At the liquid surface, the partial pressure of A is dictated by the temperature. For water, it would be 12.8 mm Hg (1.7 kPa) at 15°C. Some distance away the partial pressure is lower,

and the concentration gradient causes diffusion of A away from the surface. Similarly, a concentration gradient for B must exist, the concentration being lowest at the surface. Diffusion of this component takes place toward the surface. There is, however, no overall transport B so that diffusional movement must be balanced by bulk flow away from the surface. The total flow of A is, therefore, the diffusional flow of A plus the transfer of A associated with this bulk movement.

Molecular Diffusion in Liquids

Equations describing molecular diffusion in liquids are similar to those applied to gases. The rate of diffusion of material A in a liquid is given by Eq. 40.

$$N_A = D \frac{dC_A}{dx}$$

Fick's law for steady-state equimolar counterdiffusion is then expression by Eq. 44

$$N_A = -D \frac{C_{A2} - C_{A1}}{x_2 - x_1} \quad (44)$$

where C_{A2} and C_{A1} are the molar concentrations at points x_2 and x_1 respectively.

Equations for diffusion through a layer of stagnant liquid can also be developed. The applicability of these equations is, however, limited because diffusivity in a liquid varies with concentration. In addition, unless the solutions are very dilute, the total molar concentration varies from point to point. These complications do not arise with diffusion in gases.

Diffusivities in liquids are very much lower than diffusivities in gases, commonly by a factor of 10^4 .

Mass Transfer in Turbulent and Laminar Flow

As already explained, movement of molecules across the streamlines of a fluid in laminar flow can occur only by molecular diffusion. If the concentration of a component A varies in a direction normal to the streamlines, the molar rate of diffusion is given by Eq. 44.

When a fluid flows over a surface, the surface retards the adjacent fluid region, forming a boundary layer. If the flow throughout the fluid is laminar, the equation for molecular diffusion may be used to evaluate the mass transferred across the boundary layer. In most important cases, however, the flow in the bulk of the fluid is turbulent. The boundary layer is then considered to consist of three distinct flow regimes. In the region of the boundary layer most distant from the surface, flow is

Fig. 6 Mass transfer at (a) a boundary and (b) an interface.

turbulent, and mass transfer is the result of the interchange of large portions of the fluid. Mass interchange is rapid and concentration gradients are low. As the surface is approached, a transition from turbulent to laminar flow occurs in the transition or buffer region. In this region, mass transfer by eddy diffusion and molecular diffusion are of comparable magnitude. In a fluid layer at the surface, a fraction of a millimeter thick, laminar flow conditions persist. This laminar sublayer, in which transfer occurs by molecular diffusion only, offers the main resistance to mass transfer as shown in Fig. 6(a). As flow becomes more turbulent, the thickness of the laminar sublayer and its resistance to mass transfer decrease.

An approach to the evaluation of the rate of mass transfer under these conditions lies in the postulation of a film, the thickness of which offers the same resistance to mass transfer as the combined laminar, buffer, and turbulent regions. The analogy with heat transfer by conduction and convection is exact and quantitative relations between heat and mass transfer can be developed for some situations. This, however, is not attempted here. The postulate of an effective film is explained by Fig. 6(b). As a gas flows over a surface, equimolecular counterdiffusion of components A and B occurs, A away from the surface and B toward the surface. The variation in partial pressure of A with distance from the surface is shown in Fig. 6a. At the surface, the value of P_{Ai} , a linear fall to P_{Ab} occurs over the laminar sublayer. Beyond this, the partial pressure falls less steeply to the value P_A at the edge of the boundary layer. A value slightly higher than this is P_{Ag} , the average partial pressure of A in the entire system. In general, the gas content of the laminar layer is so small that P_A and P_{Ag} are virtually equal. If the molecular diffusion were solely responsible for diffusion, the partial pressure P_{Ag} would be reached at some

fictional distance x' from the surface, over which the concentration gradient $(P_{Ai} - P_{Ag})/x'$ exists. The molar rate of mass transfer would then be

$$N_A = \frac{D}{RT} \cdot \frac{P_{Ai} - P_{Ag}}{x}$$

However, x' is not known, and Eq. 45 may be written as

$$N_A = -\frac{k_g}{RT}(P_{Ai} - P_{Ag}) \quad (45)$$

where k_g , is a mass transfer coefficient, the units of which are cm sec^{-1} . As $C_A = P_A/RT$, it can also be written as

$$N_A = k_g(C_{Ai} - C_{Ag})$$

where C_{Ai} and C_{Ag} are the gas concentrations at either side of the film. Similar equations describe the diffusion of B in the opposite direction.

Diffusion across a liquid film is described by Eq. 46

$$N_A = k_l(C_{Ai} - C_{Al}) \quad (46)$$

where C_{Ai} is the concentration of component A at the interface and C_{Al} is its concentration in the bulk of the phase.

In all cases, the mass-transfer coefficient depends upon the diffusivity of the transferred material and the thickness of the effective film. The latter is largely determined by the Reynolds number of the moving fluid, that is, its average velocity, density, and viscosity, and some linear dimension of the system. Dimensional analysis gives the following relation:

$$\frac{kd}{D} = \text{const}(Re)^q \left(\frac{\eta}{\rho D} \right)^r$$

where Re is the Reynolds number, k the mass transfer coefficient, D the diffusivity, and d a dimension characterizing the geometry of the system.

This relation is analogous to the expression for the heat transfer by forced convection given earlier. The dimensionless group kd/D corresponds to the Nusselt group in heat transfer. The parameter $\eta/\rho D$ is known as the Schmidt number and is the mass-transfer counterpart of the Prandtl number. For example, the evaporation of a thin liquid film at the wall of a pipe into a turbulent gas is described by the equation

$$\frac{kd}{D} = 0.023 Re^{0.8} Sc^{0.33}$$

where Sc is the Schmidt number. Although this equation expresses experimental data, comparison with Eq. 41

again demonstrates the fundamental relation of heat and mass transfer.

Similar relations have been developed empirically for other situations. The flow of gases normal to and parallel to liquid surfaces can be applied to drying processes, and the agitation of solids in liquids can provide information for crystallization or dissolution.

Interfacial Mass Transfer

On a macroscopic scale, the interface can be regarded as a discrete boundary. On the molecular scale, however, the change from one place to another takes place over several molecular diameters. Due to movement of molecules, this region is in a state of violent change, the whole surface layer changing many times a second. Transfer of molecules at the actual interface is, therefore, virtually instantaneous and the two phases are, at this point in equilibrium.

As the interface offers no resistance, mass transfer between phases can be regarded as the transfer of a component from one bulk phase to another through two films in contact, each characterized by a mass-transfer coefficient. This is the two-film theory and the simplest of the theories of interfacial mass transfer. For the transfer of a component from a gas to a liquid, the theory is described in Fig. 6b. Across the gas film, the concentration, expressed as partial pressure, falls from a bulk concentration P_{Ag} to an interfacial concentration P_{Ai} . In the liquid, the concentration falls from an interfacial value C_{Ai} to bulk value C_{Al} .

At the interface, equilibrium conditions exist. The break in the curve is due to the different affinity of component A for the two phases and the different units expressing concentration. The bulk phases are not, of course, at equilibrium and it is the degree of displacement from equilibrium conditions that provides the driving force for mass transfer. If these conditions are known, an overall mass-transfer coefficient can be calculated and used to estimate the mass-transfer rate.

Transfer of a component from one mixed phase to another, as described above, occurs in several processes. Liquid-liquid extraction, leaching, gas absorption, and distillation are examples. In other processes such as drying, crystallization, and dissolution, one phase may consist of only one component. Concentration gradients are set up in one phase only, with the concentration at the interface given by the relevant equilibrium conditions. In drying, for example, a layer of air in equilibrium (i.e., saturated) with the liquid is postulated at the liquid surface and mass transfer to a turbulent air stream is described by Eq. 44, the

interfacial concentration being the saturation concentration. The rate of solution is determined by the difference between the interfacial concentration and the concentration in the bulk solution, and the mass-transfer coefficient.

VACCINES

Introduction

The concept of vaccination was introduced in the late 18th century by Edward Jenner when he used cowpox virus as a vaccine to protect humans against smallpox virus infections. This led to the development of vaccines over the next 2 centuries to provide protection against various bacterial and viral pathogens. Undoubtedly, the effective vaccination against infectious diseases is the best method of reducing suffering of human and animals caused by viral, bacterial, and parasitic infections. Over the last 200 years, the technology of vaccine development and production has not changed significantly. This usually involves the use of either a killed pathogen combined with an adjuvant or a live pathogen with reduced virulence. Apart from the tremendous success of killed and attenuated virus vaccines over the years, many of such vaccines do not provide satisfactory protection, and there are a number of other disadvantages associated with these vaccines. Additionally, there are important pathogens against which attempts to develop effective vaccines using traditional approaches were unsuccessful. Various protective viral antigens (envelope and/or capsid proteins or glycoproteins and other viral proteins) and bacterial antigens (surface, internal, or fimbria proteins; bacterial polysaccharides; bacterial toxins; and other proteins involved in bacterial metabolism) have been identified as potential vaccine candidates. These protective antigens are used by various means to develop effective vaccines. The field of vaccine technology is not limited to infectious diseases but has shown potential in other areas, such as cancer treatment, reproduction, and modulation of animal productivity. An overview of vaccine strategies is depicted in Fig. 1.

Conventional Vaccines

Inactivated vaccines

Inactivated (killed) pathogenic organisms can be used in vaccines. This is the simplest way to produce vaccines,

provided the organisms can be cultured easily. Therefore, this method is often first tested to develop a potential-vaccine. As with any other technique of vaccine production, this procedure is only good for some organisms. There are a number of methods of inactivating pathogenic organisms; the most common are treatment with chemicals (formalin, formaldehyde, or propiolactate), heat, or γ -irradiation. In some instances, the procedure of inactivation may enhance antigenicity of some antigens important in protection. Inactivated vaccines usually result in good humoral immune response after multiple inoculations. Because inactivated vaccines in general fail to elicit effective mucosal and cell-mediated immune responses, they may provide limited protection against mucosal and intracellular pathogens. Failure to inactivate the pathogenic organisms completely could result in disease instead of protection. During the 1950s, some lots of poliovirus vaccine were not inactivated completely (1, 2). Now, the methods used to detect residual infectivity are more stringent, therefore, inactivated vaccines are considered safe with extremely low or no chance of infection.

There have been instances in which inactivated vaccines led to atypical disease or enhanced disease severity. For example, in the 1960s, formalin-inactivated respiratory syncytial virus (RSV) vaccine actually enhanced the disease symptoms when vaccinated children were naturally exposed to RSV (3, 4). It was later discovered that a change in the antigenicity of RSV F and G glycoproteins (5) resulted not only in alteration in humoral immune response but also in the Th1 and Th2 components of the CD4⁺ T-cell response to RSV (6).

Live attenuated vaccines

Mostly attenuated organisms are being used as live virus vaccines; however, in some instances, even virulent organisms could be used, provided they are not administered via the natural route of infection. For example, human adenovirus types 4 and 7 may cause acute respiratory infections in humans when administered via the oronasal route but provide protection when given orally in enteric-coated capsules (7).

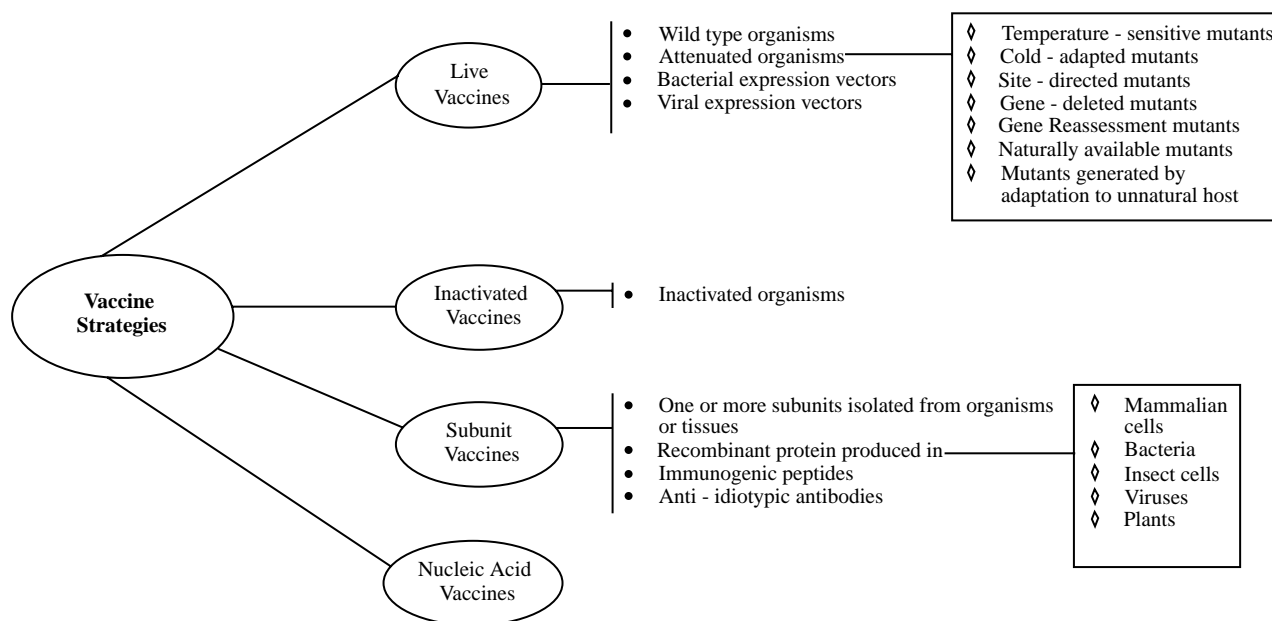

Fig. 1 Overview of vaccine strategies.

There are different ways to attenuate pathogens for vaccine production. Attenuation of organisms can be achieved by growing them under abnormal conditions, which include cultivation in unnatural hosts or cell lines. Some organisms are attenuated when they replicate at different pH levels and/or temperatures. In cells infected with multiple viruses with a segmented genome (e.g., influenza virus, reovirus), genome segments are randomly recombined in the progeny. This process of recombination is known as reassortment and is also useful in generating attenuated viruses. A natural pathogen of one host may be attenuated for another host, e.g., vaccinia virus worked as an attenuated vaccine for smallpox virus eradication program during the 1960s and 1970s, and turkey herpesvirus works as an attenuated vaccine for Marek's disease virus (a chicken herpesvirus). In an inoculated host, the attenuated organism replicates without causing disease symptoms, thereby leading to induction of immune response somewhat similar to the natural infection with the disease-causing organism. The Bacille Camet-Guerin (BCG) strain of *Mycobacterium tuberculosis* was attenuated after more than 200 passages on media containing increasing amounts of bile. The Sabin poliovirus vaccine was attenuated by a number of passages in monkeys and in monkey kidney epithelial cells (8). Measles virus was initially adapted to monkey kidney cells and subsequently attenuated in duck embryo and human tissue culture cell lines (9–11).

Temperature-sensitive (*ts*) mutants have proven to be the most useful type of mutants for a number of viruses and bacteria because of their conditional-lethal phenotype. The (*ts*) mutants are produced by alteration in the nucleotide sequence of a gene so that the resulting protein product of the gene is unable to assume or maintain its functional configuration at the nonpermissive (37–39°C) temperature. The protein, however, is able to assume a functional configuration at the permissive temperature (32–34°C), e.g., herpesviruses, adenoviruses, and influenza viruses. Thus, these mutants can replicate in mucosal sites with a lower temperature, e.g., the nasal cavity, but are unable to cause systemic infections and disease.

A number of advantages associated with live vaccines are that: 1) they are cheap to produce because the inoculum dose is relatively less, 2) they require fewer inoculations, 3) they do not require adjuvants, 4) they elicit both humoral and cell-mediated immune responses, and 5) they can be inoculated by the natural route of infection. Some of the disadvantages associated with live vaccines are that 1) they are usually less stable than inactivated vaccines and may require refrigeration for storage, 2) some of these vaccines under certain situations may revert to virulent form in the host and thereby lead to clinical disease, 3) they may not be recommended for immunosuppressed, immature, older, or pregnant hosts, 4) they may have a low level of residual virulence, and 5) they may be contaminated with other adventitious organisms.

Recombinant Vaccines

Recombinant vector vaccines

Viral vectors: For the development of an effective vaccine strategy for protection against mucosal pathogens such as respiratory and enteric viruses, a vaccine-delivery system that can induce a protective mucosal immunity in the form of secretory IgA antibody, in addition to a systemic immune response, is extremely important. The route of vaccine delivery also plays an important role in determining the type of resultant immunity induced. A number of viruses, such as adenoviruses, poxviruses, herpesviruses, picornaviruses, togaviruses, orthomyxoviruses, paramyxoviruses, and others, have demonstrated considerable potential as vectors for antigen delivery at mucosal surfaces (12). Immunogenic foreign epitopes can be expressed on the virus surface by modifying the viral capsid or envelope protein (13). A wide variety of foreign viral antigens has been expressed in viral vectors, and vaccination-challenge studies in experimental animals have demonstrated moderate to complete protection. Immunization with such vectors leads to the foreign viral antigen expression similar to that of natural infection without causing disease. Antigenic peptides are expressed along with major histocompatibility (MHC) class I and class II antigens and, thus, result in both humoral and cytotoxic T-cell responses.

Both adenovirus-and poxvirus-based vectors have a number of common advantages including that 1) vector construction is easy, ii) relatively high levels of foreign protein expression are easily attained, 3) relative thermostability, 4) they have a large capacity for foreign DNA insertion, 5) vector derivatives are nonpathogenic, and 6) they have a wide host range. More than one foreign antigen can be expressed in the same vector to provide protection against a number of diseases by inoculation with a single vector.

Vaccinia virus expressing rabies glycoprotein has been licensed for use to control rabies in the wildlife population, especially raccoons, foxes, skunks, and coyotes (14). Baits containing a live vaccinia-rabies glycoprotein recombinant virus vaccine are distributed in the rabies endemic area with the intention that rabies-susceptible wild animals that eat these baits will become immunized against rabies virus (15), and this approach has demonstrated satisfactory results. Vaccinia virus expressing the F and H gene of rinderpest virus has shown potential for its use to control rinderpest in developing countries (16, 17).

To increase the safety of viral vectors for immunocompromised hosts and to control their indiscriminate spread, replication defective viral vectors have been developed. These vectors can be grown to high titers in

vitro, but they are defective for in vivo replication. Replication-defective vectors undergo an abortive infection in an inoculated host that leads to foreign antigen expression similar to replication-competent vectors. Replication-defective adenovirus vectors are generated by deleting the early region 1 (E1) genes (18,19). E1-deleted vectors can be grown in an E1-complementing cell line, and animals immunized with such vectors elicit a protective immune response (20). Avian poxviruses grow normally in avian cells but would result in an abortive infection in mammalian hosts. Dogs and cats immunized with an avipox-rabies glycoprotein recombinant are protected against rabies virus infection (21).

Bacterial vectors: Similar to viral expression vectors, attenuated bacteria can be developed as vectors for foreign gene expression and delivery for the purpose of multivalent vaccines. Immunogenic foreign epitopes can be expressed on bacteria surfaces by modifying cell surface proteins, fimbria, or flagella. It has been demonstrated that *M. bovis* BCG strain induces both strong humoral and cell-mediated immunity, therefore, it has been developed as a delivery vector with the assumption that foreign proteins expressed by *M. bovis* in inoculated individuals will also raise a strong protective immune response (22). Because *Salmonella* and *Vibrio* colonize in the intestinal tract, attenuated strains of these bacteria were developed as vectors for mucosal delivery (23–26).

Various bacterial vectors have been used to express a number of bacterial (*B. pertussis*, *S. pneumoniae*, *Y. pestis*, and *L. monocytogenes*), viral (herpesvirus, influenza virus, human immunodeficiency virus, simian immunodeficiency virus, and hepatitis B virus), and parasitic (*S. mansoni*, and *L. major*) antigens (26). Significant improvements in attenuation of bacteria, and the stability, localization, and expression levels of heterologous antigens are required to market the bacterial vector-based vaccines for use in humans or animals.

To enhance foreign gene expression, “balanced lethal,” plasmid-based expression vehicles have been developed (27). A foreign antigen may form inclusion bodies or localize in intracellular compartment of the vector thereby affecting the type, levels, and duration of immune response elicited against the antigen. The *Escherichia coli* α -hemolysin secretion system (HSS) that includes HlyB, HlyD, and TolC is involved in exporting the HlyA-fused foreign antigens to extracellular compartment (28). Using the HSS system for attenuated *Shigella dysenteriae*, the expression and secretion of Shiga toxin-B subunit were obtained (29).

Gene-deleted vaccines

Many attenuated vaccines are derived after introduction of random mutations in the genomes of various pathogens. In

situations in which these random mutations may be point mutations, attenuated organisms may regain virulence owing to back mutations. Because of our increased understanding of virulence of various pathogens at the molecular level, one or more genes responsible for virulence has been identified in many pathogens. The genes associated with virulence may be genes involved with nucleic acid replication and other nonstructural and structural components of the organism. This has made it possible to delete one or more of these genes involved in virulence—another strategy to produce safer attenuated vaccines.

Pseudorabies virus has been attenuated by deleting genes associated with viral virulence. These genes include the thymidine kinase gene (nonstructural protein) involved in viral DNA replication and the gC, gG, and gE genes (nonessential glycoproteins) involved in virus assembly (30, 31). A gene-deleted vaccine of pseudorabies virus has proved highly effective in controlling this viral infection under field conditions. It has been demonstrated that *Salmonella typhimurium* aroA, aroB, and aroC deletion mutants fail to grow in its host because of the absence of aromatic amino acid production. These genes have been targeted to reduce the virulence of the bacterium. *S. typhimurium* gene-deleted mutants are capable of replication at least for a short period in its host, thus raising a protective immune response (32). Vaccination with gene-deleted vaccines also allows eradication of wild-type pathogens from the population. Because antibodies against the deleted gene product will only be developed in infected animals, it is feasible to differentiate between vaccinated and naturally infected animals (33, 34). The process of gene deletion not only attenuates the pathogen but also offers a unique opportunity to insert foreign genes for developing viral or bacterial-vectored vaccines.

Subunit vaccines

A subunit vaccine consists of one or more immunogenic epitopes, proteins, or other components of a pathogenic organism. Immunogenic epitopes can be chemically synthesized and are known as peptide vaccines, e.g., peptide vaccine candidates for foot-and-mouth disease virus (35, 36). The pathogen could be disrupted, and one or more immunogenic proteins such as bacterial cell wall proteins; flagella or pili; and viral envelope, capsid, or nucleoproteins can be purified. The isolation of such components in purified form is sometimes cumbersome and expensive. However, bacterial exotoxins can be easily purified, inactivated, and used as toxoid vaccines.

A number of expression systems including bacteria, yeasts, mammalian cells, insect cells, and plants are now

available for foreign protein expression. High amounts of a foreign protein can be produced in a bacterial-expression system at a low cost. Because scale-up and downstream processing have been well worked out for bacterial-expression systems, they are usually first tested for subunit vaccine production. Many of the immunogenic proteins, especially of viral origin, require secondary modifications that are important for their antigenicity. A bacterial-expression system may produce proteins of altered immunogenicity because the bacterial system lacks many posttranslational processes. However, some viral glycoproteins expressed in bacteria induce protective immunity, e.g., the gp 70 gene of feline leukemia virus (37). A yeast-expressed hepatitis B virus surface antigen (HbsAg)-based subunit vaccine is currently in use for humans and has demonstrated excellent protection against hepatitis B virus infection (38). This vaccine is an excellent example of the potential of recombinant subunit vaccines for providing protection against many viral and bacterial infections.

Because mammalian cells are known to process viral glycoproteins to their functional form by secondary modifications, they are considered one of the means to produce viral antigens for subunit vaccine production. However, the expression of such proteins in mammalian cells is usually too low. It was demonstrated that the stable expression of the transmembrane anchor-deleted form of many viral glycoproteins in mammalian cells results in the secretion of truncated products in the medium in large quantities that could be used as a subunit vaccine without further purification. However, the removal of transmembrane anchor may potentially alter antigenicity of the secreted protein. A number of viral glycoproteins that were expressed either in mammalian or in insect cells and secreted in form of proteins were suitable for providing protective immune response include F and G genes of respiratory syncytial virus (39), the HN and F genes of parainfluenza virus (40), and the gD gene of bovine herpesvirus type 1 (41).

Immunogenic antigen production in plants: In the past decade, significant progress has been made in the stable integration and expression of a wide variety of genes in plant cells, resulting in the creation of novel plants for agricultural and industrial use. The inserted genes confer resistance to insect pathogen and herbicides; enhanced tolerance to drought, salt, and frost; and improved agricultural production. Undoubtedly, improvements in plant attributes by genetic engineering will have a great impact on agriculture production. However, it has been estimated that the major economic (over 90%) gain of plant biotechnology will result from the use of plants as bioreactors to produce high-valued products such as vaccines, industrial enzymes, and other pharmaceuticals.

Production of subunit vaccines in mammalian cells is usually expensive because of the low level of foreign gene expression and high processing cost. High levels of foreign gene expression can be obtained in bacteria and yeast, but many animal viral or mammalian proteins expressed in these systems fail to undergo proper secondary modifications such as glycosylation, phosphorylation, sulfation, etc. Therefore, these recombinant proteins may have altered antigenicity. Because most mechanisms regulating secondary modifications of proteins are present in plants, transgenic plants offer an attractive alternative to produce functional viral, bacterial, or parasitic proteins in large quantities at a very low cost for subunit vaccine production (42). Similarly, the production of functional multimeric antibody molecules in plants has made it possible to manufacture antibodies in bulk amounts for passive immunization (43).

Two major strategies have been devised to produce foreign proteins in plants. These are: 1) the stable integration of chimeric gene into the plant genome under a suitable constitutive or inducible plant promoters (44, 45), and 2) manipulation of plant pathogenic viruses (46). Foreign protein expression in plants usually range from 0.01 to 1% of the total plant protein.

The hepatitis B virus (HBV) surface antigen HBsAg produced in transgenic tobacco elicits an immune response when injected in mice (47). Mice fed transgenic potato tuber expressing B subunit of heat-labile enterotoxin (LT-B) of enterotoxigenic *E. coli* developed antibodies to LT-B, particularly IgA antibodies (44). Dalsgaard et al. (46) demonstrated that immunization of mink with the VP2 capsid protein of mink enteritis virus, expressed in cowpea after infection with modified cowpea mosaic virus, elicited a protective immune response. Protection against challenge with virulent foot-and-mouth disease virus (FMDV) in mice inoculated with the structural protein VP1 of FMDV produced in transgenic *Arabidopsis* has been shown (45). It has been hypothesized that transgenic plants could serve as “edible vaccine,” thereby providing a very inexpensive mean of oral immunization (48).

Anti-idiotypic vaccines

Another approach to provide protective immune response is the use of anti-idiotypic antibodies as vaccines. Antibodies have unique sequences in the variable (V) region in their binding site known as “idiotypic determinants”. Some of the idiotypic determinants make up the antigen-binding site (paratope) of the antibody. The part of the antibody that binds to the antigen is called a paratope. Antibodies to a specific paratope of an idiotypic mimic the epitope of immunizing antigen and are known as anti-idiotypic antibodies. Thus, anti-idiotypic antibodies are mirror images of

antigens and can be used instead of immunogens to elicit a protective immune response. Monoclonal anti-idiotypic antibodies could serve as a source of antigen. Anti-idiotypic vaccines are useful in cases in which actual antigen is poorly immunogenic or similar to host antigens. Some of the pathogens against which anti-idiotypic vaccines have been tested include *Listeria monocytogenes*, *Streptococcus pneumoniae*, hepatitis B virus, Semliki forest virus, and Sendai virus (49, 50). This type of vaccine is still in the developmental stage.

DNA Vaccines

Immunization of mammalian hosts with a plasmid DNA containing a gene under control of a heterologous promoter has introduced a new approach in the area of recombinant vaccine design. The introduced DNA is taken up by cells, and the gene of interest is expressed. The cells expressing the foreign antigen are recognized by the host immune system, leading to humoral and cell-mediated immune responses. DNA vaccines can also be called polynucleotide vaccines or nucleic acid (NA) vaccines. Such vaccines appear to have the primary advantages of both attenuated and inactivated vaccines but without their known limitations. NA vaccines elicit an immune response similar to that obtained with live attenuated vaccines. They also provide safety similar to that of inactivated vaccines, however, without the obvious side effects of adjuvants or animal-derived proteins.

The concept of NA vaccine evolved from initial studies in experimental animals in which the inoculation with naked plasmid DNA resulted in a protective immune response (51). After inoculation into a muscle, the efficiency of cellular uptake of the naked DNA is poor, and a large portion of the DNA is degraded before it reaches the nucleus for transcription. To increase the efficiency of DNA uptake by host cells and to reduce DNA degradation within the cell, a number of delivery systems,

Fig. 2 Methods of nucleic acid delivery.

Fig. 3 β -Galactosidase expression in tissues of mice inoculated orally with alginate microspheres containing plasmid DNA: (A) liver, (B) intestine, and (C) spleen sections from the animal inoculated with microspheres containing bovine adenovirus type 3 (BAd3). (D) Liver, (E) intestine, and (F) spleen sections from the animal inoculated with microspheres containing LacZ plasmid +, BAd3. (From Ref. 57.)

such as bombardment with gold microparticles coated with NA (52, 53), incorporation of NA into liposomes and other polycationic lipids (54, 55), biological erodable polymers (56), and others, have been developed (Fig. 2). Recently, it has been demonstrated that alginate microspheres can be used for the encapsulation, delivery, and expression of plasmid DNA (57) (Fig. 3). Inoculation of mice with microspheres containing both plasmid DNA and bovine adenovirus type 3 (BAd3) resulted in a significant increase in transgene expression compared with those inoculated with microspheres containing only the plasmid DNA. As with other delivery systems, alginate microspheres led to a stronger mucosal or systemic immune response, depending on route of inoculation (58). Because alginate microspheres are most likely taken up by macrophages and dendritic cells, it may have a positive effect on the type of immune response elicited.

A number of factors that have an impact on the level and type of immune response produced by an NA vaccine

include the type of immunogen, the dosage and number of inoculations, the heterologous regulatory sequences, the delivery system, the route of inoculation, and the presence or absence of immunomodulatory molecules. A variety of immunogenic antigens including HIV-1, SIV, HTLV-1, influenza virus, hepatitis B virus, hepatitis C virus, herpesvirus, *M. tuberculosis*, *Leishmania*, malaria, and many more have been expressed by NA vaccines and have demonstrated encouraging results (59–63).

Adjuvants

Adjuvants are compounds that, when administered in combination with antigens, enhance the immune response to those antigens. This enhanced immunogenicity can be measured as an increase of antigen-specific antibody levels in serum and/or mucosal secretions, a response against an increased number of epitopes, an increase of cell-mediated immune responses, or a combination thereof. Adjuvants

are particularly important for the induction of protective immune responses against weak immunogens such as subunit vaccines. The mechanisms by which adjuvants enhance the immunogenicity of antigens are not completely understood, but they include immunostimulation, altered processing of antigens, and sustained release of antigens (depot effect). A different type of immune response is obtained by administration of antigens via the oral route, and this has different delivery requirements.

Many compounds can act as adjuvants. Their classification is made difficult by the variety in chemical composition and the overlapping, often poorly understood, mechanisms of action. Only aluminum adjuvants are approved by the FDA for use in human vaccines. Quil A is a saponin that is commonly used as an adjuvant in veterinary vaccines and is also a component of immune-stimulating complexes (ISCOM). These adjuvants are addressed in some detail below. A detailed discussion of other types of adjuvants can be found in recent books (64–66) and reviews (67) on this subject.

Immunostimulation

The immune system can be divided into the adaptive immune system, comprising of B and T lymphocytes, and the innate immune system, which includes neutrophils, macrophages, dendritic cells, and soluble factors such as the complement system. The innate immune system plays a critical role in the activation of the adaptive immune system. Dendritic cells are antigen-presenting cells that integrate the signals from the innate immune system and activate T-cells and possibly B-cells. T-cells have antigen-specific receptors that recognize peptides displayed by MHC I molecules ($CD8^+$ cytotoxic T-cells) and MHC II molecules ($CD4^+$ T helper cells). Engagement of the antigen-specific T-cell receptor is not sufficient, and T-cells also need to receive costimulatory signals delivered via CD28 and CD40-ligand. Dendritic cells express both MHC I and MHC II and, on activation, increase the expression of the costimulatory molecules CD80 and CD86 (ligands for CD28) and CD40. The signals that activate dendritic cells include microbial molecules. The innate immune system is equipped with receptors (called pattern-recognition receptors) that can recognize molecules that are expressed by pathogens, but not by mammalian cells, and alert the innate immune system on infection. These molecules, pathogen-associated molecular patterns, include lipopolysaccharides (LPS), mannose, and bacterial DNA with unmethylated CpG motifs. In addition, dendritic cells are stimulated by host cell components that are expressed and/or released by cells when they undergo stress and pathologic cell death (necrosis). The identity of these components, called danger signals, is uncertain but

may include heat shock proteins. The microbial molecules and danger signals can directly activate dendritic cells, or they can activate other components of the innate immune system resulting in the secretion of cytokines and other mediators that activate dendritic cells. The activated dendritic cells, in turn, activate T- and B-cells.

Immune responses can be divided into type 1 and type 2, based on the pattern of cytokine secretion and functional outcome of the immune response. Type 1 immune responses are characterized by secretion of IFN- γ , production of IgG2a in mice, and activation of macrophages, NK cells, and cytotoxic T-cells. Type 2 responses are characterized by secretion of IL-4, IL-5, and IL-13 and by IgG1 and IgE production. The responses are reciprocally regulated. How the polarization of the immune response toward type 1 or type 2 is determined is not exactly understood. IL-12 is an important factor that drives the type 1 response, and IL-4 is implicated in the type 2 response. Microbial products such as LPS and bacterial DNA stimulate the secretion of IL-12 by dendritic cells and preferentially induce type 1 immune responses.

It is likely that the primary mechanism by which adjuvants stimulate the immune response is by direct or indirect signaling through pattern-recognition and danger signal receptors. Very strong adjuvants are often composed of or include microbial components such as LPS and mycobacteria or derivatives thereof. These type of adjuvants bind to pattern-recognition receptors to stimulate IL-12 production and a type 1 immune response. Coadministration of cytokines can directly activate and influence dendritic cells and the outcome of the immune response. This was clearly demonstrated with an experimental *Leishmania* vaccine using IL-12 as an adjuvant. Immunization of genetically susceptible BALB/c mice with a *Leishmania* antigen did not result in protection, but when IL-12 was injected with the antigen, the mice became markedly resistant to infection. The effect of IL-12 correlated with increased IFN- γ and decreased IL-4 secretion by antigen-specific T-cells in vitro.

Altered processing of antigens

Most T-cells that carry the α - β -T-cell receptor do not recognize and react with intact proteins. Instead, the T-cells recognize small peptides that are derived from proteins and that are linked to MHC I and MHC II molecules. The MHC I-linked peptides are generated in the cytoplasm (endogenous pathway) and recognized by $CD8^+$ T-cells. Proteins in the cytoplasm are degraded by a complex of proteolytic enzymes, the proteasome, and the peptides are transported into the rough endoplasmic reticulum where they associate with MHC I molecules. Peptide binding

stabilizes the MHC I molecules, and the complexes are transported to the cell surface. In contrast, proteins that enter cells by endocytosis are partially degraded into peptides in endosomal vesicles. The peptides bind MHC II molecules that have been transported from the endoplasmic reticulum to the endosomes. The MHC II-peptide complexes are then displayed on the cell surface and are available for recognition by CD4⁺ T-cells.

Vaccines that contain single proteins or inactivated pathogens can readily activate CD4⁺ T-cells because the antigens are endocytosed and processed by MHC II-positive antigen-presenting cells. Activation of the CD4⁺ T-cells can result in a type 1 or a type 2 immune response, depending on the type of adjuvant included. However, such vaccines usually do not activate CD8⁺ cytotoxic T-cells because activation of CD8⁺ T-cells requires processing of antigen via the endogenous pathway. Certain adjuvant formulations such as liposomes, the saponin QS-21, and poly-(lactic-co-glycolic acid) (PLGA) are able to induce cytotoxic T-cell responses to protein antigens (68). These adjuvants appear to target some of the injected antigens into the cytosol of antigen-presenting cells for processing via the endogenous pathway. The mechanism by which this occurs is not known.

Sustained release of antigens

The slow and continued release of antigens has been postulated to induce a strong immune response through continued activation of the immune system. This may contribute to the adjuvant effect of aluminum-based adjuvants and mineral oils. Newer technologies may allow for the design of vaccines that release antigens from a depot at certain time intervals after a single injection. One example is the use of poly PLGA microspheres for encapsulation of antigens. By varying the polymer composition and size of the microspheres, the release of antigen can be varied. Pulsatile release of antigen can be attained by combining multiple variations of PLGA microspheres in a single dose of the vaccine (69). Relatively little is known about the desired pattern of antigen release to obtain a maximal response. It was recently suggested that continued release of antigen is not desirable for the induction of strong memory cell responses. Mathematical models may help design appropriate strategies for the release of antigens from depots after a single injection (70).

Aluminum

Aluminum adjuvants in human vaccines are either aluminum hydroxyphosphate (commonly referred to as aluminum phosphate) or aluminum oxyhydroxide (aluminum hydroxide) (71). Aluminum-based vaccines are prepared

by adsorption of antigen to commercial aluminum hydroxide or aluminum phosphate gels or by mixing antigen with alum (potassium aluminum sulfate), resulting in precipitation. The alum-precipitated adjuvants resemble aluminum phosphate in their chemical and physical properties (71). The surface charge and morphology of the aluminum adjuvants affect their adsorptive capacity. The rate and degree of adsorption are further dependent on the pH, ionic strength of the antigen solution, and isoelectric point of the antigen.

Aluminum adjuvants are universally used in diphtheria-tetanus-pertussis (DTP) vaccines and in most hepatitis B vaccines and have an excellent safety record. They are not ideal adjuvants, however, because the enhancement of the immune response is relatively weak, they are not effective with all antigens, and, most important, they only enhance the humoral (type 2) immune response and have little effect on the cell-mediated (type 1) immune response.

The mechanism by which aluminum enhances the immune response is not clear. Early studies suggested that aluminum adjuvants slowly release the adsorbed antigen over time (depot effect). However, recent experiments demonstrated that antigens are rapidly desorbed after injection in animals. Moreover, aluminum phosphate enhanced the immune response to DNA-encoded antigen after DNA immunization, clearly indicating that adsorption may not be critical to the adjuvant effect of aluminum compounds. These data indicate that aluminum enhances the immune response via other mechanisms. A satisfactory explanation of the adjuvant effect of aluminum also needs to take into account its selective mode of enhancing the immune response, i.e., a predominant type 2 immune response. Aluminum adjuvants induced differentiation toward type 2 immune responses, even in the absence of IL-4 or IL-13. Aluminum stimulated a type 1 and type 2 immune response in genetically engineered mice with a defective IL-4 and IL-13 response, suggesting that aluminum-induced IL-4 and/or IL-13 secretion suppresses the type 1 response but are dispensable for a type 2 response in intact animals (72). The lack of a type 1 immune response is a drawback for the use of aluminum in vaccines for intracellular pathogens and tumors. A recent study demonstrated that aluminum adjuvant with adsorbed IL-12 induces a strong type 1 response, indicating that it is possible to overcome the aluminum-induced suppression of type 1 responses (73).

Saponins

The saponins of the bark of the *Quillaja saponaria* Molina tree have long been known to have immunostimulatory activity. A partially purified fraction, Quil A, has reduced

toxicity and more potent adjuvant activity and is used in veterinary vaccines. Quil A can be further fractionated into fractions that have different degrees of toxicity. QS-21 is a less toxic component with strong adjuvant activity. Saponins probably act by direct stimulation of the immune system (74). They stimulate both the humoral (primarily IgG2a antibodies in the mouse) and cell-mediated immune responses. QS-21 causes protein antigens to be processed and presented via the MHC I pathway, resulting in cytotoxic T-cell responses. Cytokine analysis indicates that QS-21 stimulates type 1 cytokine production.

Immune-stimulating complexes (ISCOMs) are 30–40 nm particles consisting of Quil A, cholesterol, antigen, and phospholipids (74). They are used in a commercial vaccine for equine influenza. ISCOM-adjuvanted vaccines stimulate a strong humoral and cell-mediated immune response caused by the immunostimulatory actions of Quil A and targeting of the particles to macrophages. As with Quil A, ISCOMs target antigens for processing via the MHC I pathway, resulting in induction of cytotoxic T-cell responses.

Delivery of Vaccines

Parenteral versus mucosal route

The success of vaccination depends primarily on the method of presenting the antigen to the host immune system. Antigens have usually been delivered by parenteral (such as intravenous, intramuscular, intraperitoneal, intradermal, and subcutaneous) administration, but recent studies have shown that other routes of delivery such as intranasal, oral, and transdermal delivery have also been effective. In some cases, vaccination through mucosal routes resulted in better responses in IgA production. Because nonparenteral vaccine delivery presents many obvious advantages, numerous attempts have been made on the development of nonparenteral delivery of vaccines.

Parenteral route: Parenteral vaccination remains the immunization method of choice for most antigens because it provides more effective immune response than do any other routes of vaccination in most cases. Every year millions of people receive inactivated influenza vaccine by parenteral administration. Subcutaneous vaccination with inactivated influenza vaccine is known to induce simultaneous immune responses in the blood and upper respiratory tract of subjects. The immune response, i.e., the increase in the number of influenza virus-specific antibody-secreting cells in peripheral blood and tonsils, increased rapidly to reach a peak within 1 week after vaccination (75). Parenteral vaccination of a DNA vaccine encoding glycoprotein D of herpes simplex virus type 2

resulted in systemic cellular and humoral responses. The mucosal humoral responses generated by intramuscular and intradermal vaccination were comparable with those obtained by mucosal vaccination. The DNA vaccine was able to stimulate a response in the Peyer's patches, a major inductive site for mucosal responses (76). For many other antigens, however, the usefulness of parenteral vaccination is limited by the insufficient induction of mucosal immune responses.

Parenteral vaccination is difficult for those living in the developing countries where medical care is not well-established. Vaccination of a large number of subjects using hypodermic needles, which is a highly labor-intensive procedure requiring healthcare personnel, is not practical. The problem becomes even more significant for vaccination of millions of animals. For example, vaccination for routine control of Newcastle disease in chickens by intramuscular injection requiring individual handling of the birds is not practical (77). Recent advances in needleless injectable systems have made the parenteral vaccination easier, but it still requires individual handling. Examples of needleless injection systems are Powder-Ject[®], Medi-Jector[®], Biojector[®], Vitajet[®], Bio-Set[®], and Intraject[®]. They all use high pressure released in a very short period to deliver drugs through the skin. A jet-immunization technique was used for intraoral administration of DNA in the cheek, resulting in high IgA mucosal responses (78). The intraoral jet-injection technique for DNA vaccine delivery has the advantages of being a simple and rapid way to administer the DNA in solution and to provoke specific mucosal IgA after administration in the mucosal-associated lymphoid tissue.

The results of parenteral vaccination depend on the route of administration. For plasmid DNA vaccines, the highest levels of antibodies were induced by intramuscular and intravenous injections, although significant titers were also obtained with sublingual and intradermal delivery. Delivery to the skin by the gene gun induced exclusively IgG1 antibodies (Th2-like) at 4 weeks and only very low IgG2a levels at later times. Other routes, such as intraperitoneal, intraperineal, subcutaneous, intranasal inhalation, intranasal instillation, intrarectal, intravaginal, ocular, and oral, did not result in significant immune responses (79).

Dual-chamber syringe. For delivery of two established vaccines (e.g., polyribosyl ribitol phosphate conjugated to tetanus toxoid and diphtheria–tetanus–whole cell pertussis and inactivated poliovirus vaccine) at the same time, a dual-chamber syringe delivery system can be used. The proximal chamber may contain a vaccine in the freeze-dried solid state, and the distal chamber contains a vaccine in the liquid formulation that allows reconstitution of the

vaccine in the proximal chamber. The immune response by the dual-chamber delivery of vaccination was equivalent to that by the separate-injection method of vaccination. The dual-chamber syringe can be used for safe and effective delivery of two different vaccines that are not yet available as a single formulation for pediatric applications (80). The primary advantage of the dual-chamber syringe is that it reduces the cost of vaccine delivery and, at the same time, increases the vaccine acceptability and coverage rate of vaccines (81).

Mucosal route: Vaccination through mucosal routes provides new avenues of vaccination with a unique advantage of mucosal immunity, that may not be obtained, through parenteral vaccination. Mucosal immunization presents a realistic alternative to parenteral administration for inducing protective immune responses. Vaccination by mucosal route provides a number of advantages over parenteral vaccination. First, mucosal vaccination does not involve hypodermic needles, which are not user-friendly. Second, the total surface area of the mucosal surfaces in the gastrointestinal, respiratory, and urogenital tracts where many infectious pathogens come into contact with the host is huge. Thus, preventing infections at the mucosal surface

provides an immunological first line of defense against diseases (82). This makes priming of the mucosal-associated lymphoid tissue (MALT) by vaccination most desirable. Parenteral vaccination alone is quite often insufficient in inducing mucosal immune responses, because stimulation of the MALT usually requires direct contact between the immunogen and the mucosal surface (83). The mucosal tissues are protected by interconnected local immune system, which is essentially separated from systemic immunity (84). In a common mucosal-defense system, an antigen interacting with localized lymphoid tissue can stimulate IgA precursor cells that may then migrate to other mucosal surfaces to elicit immune reaction in other mucosal tissues. It is known that the mucosal immune system produces 70% of the body’s antibodies (85). Fig. 4 shows a schematic description of the common mucosal-immunization system. Mucosal delivery of numerous antigens by a variety of routes (oral, nasal, tracheal, and rectal) has been shown to elicit immunity at mucosal surfaces mediated by secretory IgA. The presence of MALT indicates that mucosal vaccination at a certain site in the body can be achieved by mucosal immunization at the distal site of the body. Although the mucosal and

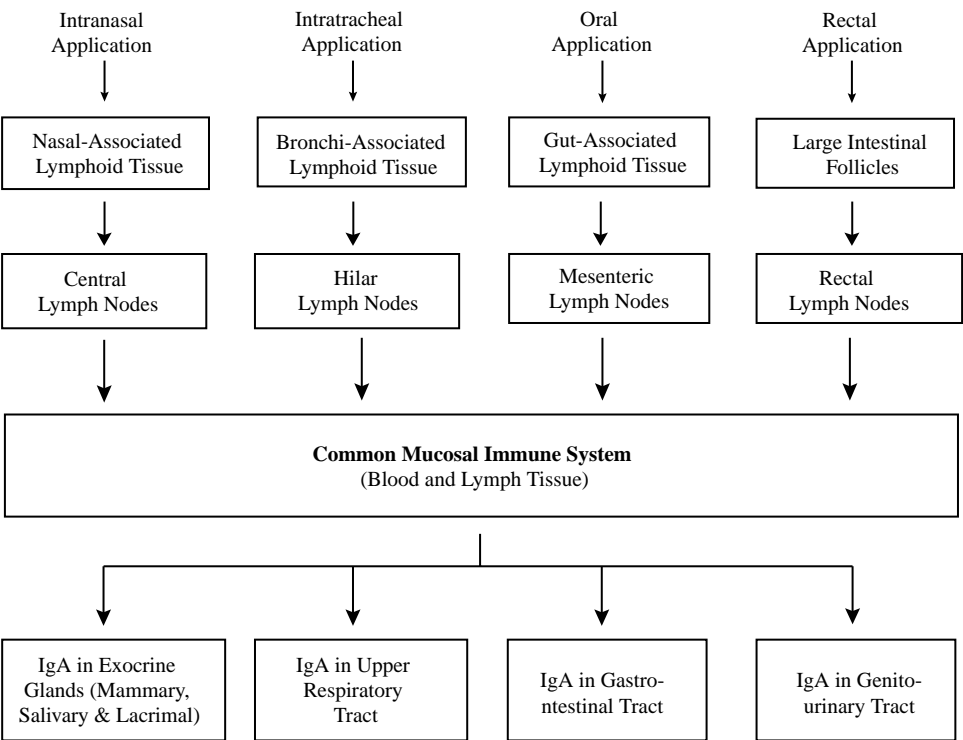

Fig. 4 Mucosal immunization and production of IgA antibodies in various mucosal surfaces via the common mucosal-immunization system. Nasal and rectal vaccinations usually result in IgA production in upper respiratory tract and genitourinary tract, respectively, whereas effector sites by oral vaccination are expected to include many mucosal surfaces.

systemic humoral immune systems function essentially independent of each other, an antigen administered by one route can modify responsiveness to subsequent immunization by an alternate route (86).

Oral vaccination of the various mucosal routes, oral vaccination is the most preferable mode of vaccination because of its ease of use and low cost of manufacturing (87). Furthermore, the gastrointestinal (GI) tract provides the largest component of the mucosal immune system that has been well-characterized. Oral administration of vaccines has high acceptability, by avoidance of injection, to individuals of all ages. Fig. 5 shows the current understanding of oral vaccination. After oral vaccination, an antigen, which is typically loaded in microspheres, is taken up by M-cells in the Peyer's patch of the gut-associated lymphoid tissue. The antigen is then passed to the macrophages and B-cells (B). These cells in turn present the antigen to T helper lymphocytes. These cells migrate into the blood via the mesenteric lymph nodes (MLN) and the thoracic duct (TD). These cells subsequently localize in the effector sites, i.e., mucosal membranes of the GI tract, upper respiratory tract, genitourinary tract, and glandular tissue. At the effector sites, the migrating B-cells develop into plasma cells that produce IgA antibodies. Polymeric IgA is then released as secretory IgA (sIgA) through epithelial cells.

The maximal intestinal immunization can be achieved by intra-Peyer's patch immunization, and thus this method can be used to screen oral vaccine candidate antigens without the added complication of simultaneously testing

oral-delivery systems (88). Immunization of subjects against *Helicobacter pylori* by intra-Peyer's patch resulted in an 84–91% reduction in *H. pylori* infection compared with unimmunized controls. The therapeutic efficacy of the recombinant *H. pylori* urease vaccine in mice was shown to be comparable with that achieved with the combined antibiotic/antacid treatment in humans. The oral vaccination is preferred to conventional treatment of ulcers because it is a very simple and quick procedure compared with long-term conventional treatment. In addition, vaccines use the defense mechanisms of the body to establish long-lasting immunity (89).

One of the limitations of oral vaccination is that it does not always induce sufficient immunity. There are a few good reasons for this. First, the GI tract is designed to digest proteins by acidic and enzymatic degradation for absorption. Because most antigens are proteins in nature, they may be degraded by enzymes in the GI tract as well as by acids in the stomach. This is why soluble antigens administered orally are not effective. Thus, prevention of the antigen degradation is the first step toward successful oral vaccination. Adding protease inhibitors before oral vaccination may induce complete immunity, but this approach is not practical. There are many different enzymes that may not be inhibited by a particular protease inhibitor, and, more important the action of protease inhibitors may not occur at the same time that the antigens are present in the GI tract. Second, the systemic uptake of antigens from the GI tract is very poor. Even after oral intake of gram quantities of antigen, only a nanogram range of antigenic material was found to pass the intestinal barrier (90). It is also possible that for certain antigens, oral vaccination may simply be less effective than parenteral vaccination in induction of systemic immunity (91). The protection resulting from oral vaccination is known to last for a relatively short period, ranging from a few months to 1 year. To obtain the desirable immunity equivalent to systemic immunization, oral vaccination requires much higher and more frequent oral doses. The use of highly effective adjuvants in oral vaccine formulation may result in strong and long-lasting immunity in mucosal tissues.

The issues of degradation of antigens in the GI tract and the poor systemic uptake of antigens from the GI tract have led to encapsulation of antigens in microparticles (also called microcapsules or microspheres). Antigens that are encapsulated in microparticles are protected from degradation, and the microparticulate nature allows better uptake by the M-cells in the Peyer's patches. A large number of studies have shown that antigens orally delivered in microparticles resulted in good mucosal immunity. It is noted here that virus itself can be regarded as a particulate vaccine-delivery system. Many viruses are

Fig. 5 Mucosal immunization by oral vaccination.

highly effective in inducing immunization after oral vaccination. Norwalk virus, which is a major cause of epidemic gastroenteritis, was immunogenic in healthy human adults even when administered without adjuvants (92). Influenza virus can also elicit immune response after oral administration. Successful oral vaccination relies on targeting of microparticles to the Peyer's patches. It is known that the surface chemistry of microparticles affects the targeting to and uptake by M-cells in the Peyer's patches (93). The exact relationships between the surface chemistry and the uptake by Peyer's patches, however, have not been fully understood. Development of better oral vaccines requires understanding of such relationships.

Intranasal vaccination route has received growing interest for noninvasive immunization. Intranasal immunization has been quite effective for various vaccine-delivery systems. Both solution and microsphere formulations tend to show good immune responses after intranasal administration. Immunization of mice with tetanus toxoid, in solution and microsphere-encapsulated formulations, resulted in high levels of specific IgG and IgA antibodies (94). Nasal vaccine delivery is known to be superior to oral delivery in inducing specific IgA and IgG antibody responses in the upper respiratory tract (95). Nasal immunization is also known to be preferable to the oral route for distant mucosal vaccination that might be used to prevent adhesion of pathogens to the urogenital tract (95). It is interesting to note that the volume of the nasally instilled vaccine is important (94). The larger-volume (e.g., 50 μ L) of microsphere suspension resulted in the higher percentage of particles entering the lungs than did the lower, volume (e.g., 10 μ L) instillation.

It is generally believed that microspheres that adhere to the nasal mucus elicit better immune response, and for this reason, many microspheres made of mucoadhesive polymers, such as chitosan, have been used extensively in the preparation of nasal vaccine formulations.

Transdermal vaccination or transcutaneous immunization, is attractive, because it does not require specially trained personnel necessary for needle injections. Topical application of antigens to intact skin has shown promising results for the administration of DNA-based vaccines. Noninvasive gene delivery by pipetting adenovirus- or liposome-complexed plasmid DNA onto the outer layer of skin was able to achieve localized transgene expression within a restricted subset of skin in mice. It also elicited an immune response against the protein encoded by the DNA (96).

For improved results, transdermal electroporation was also tried to explore the feasibility of nonadjuvant, needle-free skin immunization (97). The transdermal electroporation route elicited higher responses to a myristylated

peptide than did intradermal immunization. For diphtheria toxoid, however, the result was the opposite. It appears that transdermal electroporation is a promising technique for nonadjuvant skin immunization, especially with low-molecular-weight, weakly immunogenic antigens. Topical application of antigen and cholera toxin or bacterial exotoxin to the skin surface resulted in detectable antigen-specific IgG in plasma and mucosal secretions (98, 99). It appears that transcutaneous immunization can induce potent, protective immune responses to both systemic and mucosal challenge (100).

Pulmonary vaccination is especially useful in mass vaccination campaigns. A conventional method of pulmonary delivery of drugs using metered-dose, propellant-driven, small-particle aerosols was used to deliver killed whole bacterium vaccines. The results showed good stimulation of mucosal immunity against respiratory infections in animals (101). Recent advances in powder inhaler devices have made it possible to deliver vaccines via the pulmonary route using dry powder inhalation technologies (102). Dry powder vaccine in the size range from 1 to 5 μ m in diameter is used for the maximum alveolar (deep lung) deposition (101).

Direct gene transfer into the respiratory system can be carried out for either therapeutic or immunization purposes. Cells in the lung can take up and express plasmid DNA whether it is administered in naked form or formulated with cationic liposomes. For a given dose of DNA, the results can be improved when the DNA is mixed with the minimum amount of lipid that can complex it completely (103). Such a complex formation can be considered a formation of microparticles that can enhance cellular uptake and subsequent immune responses.

Parenteral and mucosal combination vaccination:

The combination of mucosal and systemic immunization routes (e.g., parenteral immunization followed by oral immunization or vice versa) generally induces mucosal immune responses that are superior to immunization by either route alone (91). Pigs showed some protection after intramuscular inoculation with formalin-inactivated *M. hyopneumoniae* vaccine in incomplete Freund's adjuvant and a booster inoculation with the same vaccine in microspheres onto the mucosal surface of Peyer's patches by a surgical operation (104).

Antigen delivery systems

The primary goal of antigen-delivery systems is to maintain a stable dosage form during storage and, when administered to present antigens to elicit a vigorous immune response in vivo. It is necessary to develop vaccine formulations that would preserve the antigen and deliver it

to a specific target organ over a desired period. Continuous release or multiple pulsatile release during the desired period would eliminate the inconvenience of multiple vaccine administration for obtaining satisfactory immune responses. The antigen-delivery system plays one of the most crucial roles in the outcome of the immunization. The way that antigens are delivered affects the immune response significantly. Currently, antigen-delivery systems are classified into two systems: live attenuated microorganisms and nonliving microparticulate systems.

Live attenuated organisms: Live attenuated bacteria and viruses have been used not only as vaccines but also as a delivery system that elicits humoral, mucosal, and cellular immune responses against exogenous antigens. Since the success with live attenuated oral vaccines against tuberculosis and polio more than 3 decades ago, a number of live attenuated microorganisms have been used as antigen-delivery systems. Live vaccines are relatively easy and cheap to manufacture, because they do not require purification of antigens or formulation with adjuvants (82). Attenuated strains of microorganisms can be formed spontaneously or induced by heat, chemical, or UV mutagenesis. Another advantage of the attenuated live vaccines is that they can be administered by the natural route of infection. Recently, pathogenic microorganisms have been attenuated by genetic engineering, i.e., mutating specific genes or removing some toxic genes. Because much of the infection occurs through the mucosal surfaces, live attenuated vaccines are best suited for protection against pathogens that access the body through the mucosal surfaces. Live attenuated oral vaccines are expected to provide the most convenient and effective means of vaccinating against enteric disease (105). Orally administered attenuated *Salmonella* are known to interact with the MALT (82). Other examples of live attenuated microorganism vaccines are BCG (bacilli Calmette–Guérin), adenovirus, and poliovirus.

Some viruses and bacteria are inherently quite stable. For example, polio virus can be formulated as a frozen liquid. A live poliovirus vector expressing a foreign antigen generates both antibody and cytotoxic T-lymphocyte responses in mice (106). Most live bacteria and viruses, however, are usually stored as powders after freeze-drying or lyophilization. Preserving the live state through freeze-drying often requires the presence of a stabilizer, which is selected primarily through trial and error. The most widely used nonspecific stabilizers are sugars, amino acids, polyols, and neutral salts which are known to act as bound water substitutes for maintaining the conformational integrity of proteins. An example of lyophilized vaccine products is *S. typhi* bacteria lyophilized to a powder that is encapsulated into gelatin for oral administration (107).

One of the drawbacks of using live microorganisms is that attenuated pathogens may invoke the very disease they are designed to prevent if they are insufficiently attenuated. Even if they are sufficiently attenuated, they still may cause severe infections in immunocompromised individuals. In addition, they always have a potential to revert to full virulence if lesions causing attenuation are not fully characterized (82). If pathogens are over-attenuated, they fail to trigger an appropriate immune response. Thus, it is highly important to attain the right balance between minimal virulence and maximal immunogenicity. This balance can be achieved in a normal population but may not be the same in a population with even minor defects in immune competence (108). Another aspect to notice in using live vaccines is that the distribution of live vaccines requires a cold chain that may not be readily accessible in many developing countries, and this may offset advantages of using live-vectored vaccines (109).

Nonliving microparticulate delivery systems: Nonliving immunogens generally result in immune responses of lesser magnitude and of shorter duration than do those by living immunogens (82). Nonliving immunogens are usually made of microparticulate forms to protect antigens and to improve cellular uptake. Nonliving microparticulates that can be used as antigen-delivery systems include polymeric microparticles, liposomes, virus-like particles, neosomes, and cross-linked protein crystals. The definition of microparticles should be broad enough to include all other forms, such as protein aggregates. The size of microparticles used in the vaccine area is usually less than 50 μm (110). It is common, however, to call any particles less than a few hundred micrometers microparticles. For this reason, it is important to specify the average size of microparticles for particular applications, because the size of microparticles often affect the outcome.

Polymeric microparticles and liposomes have been used extensively as controlled-release dosage forms for many drugs including antigens. They have been quite useful in oral delivery of antigens because encapsulation in microparticles can protect antigens from acidic and enzymatic degradation in the GI tract, and thus serve as a stable vaccine vehicle with extended shelf life. Delivery of antigens by microparticulate-delivery systems has the potential benefits of reducing the number of inoculations, enhancing the immune response via both parenteral and oral vaccination routes, and reducing the total antigen dose required to achieve immune protection (111). Microparticulate vaccine-delivery systems show improved immune responses because of the protection of the loaded antigens from degradation and the slow release of the

antigens. For this reason, microparticulate-delivery systems are often considered adjuvants (66).

Polymer microparticles, a large number of polymers, such as poly(methyl methacrylate), poly(butyl cyanoacrylate), poly(lactide-co-glycolide), polyaracyl starch, dextran, albumin, and alginic acid, have been used for making microparticles for vaccine delivery. All the polymers that have been used for controlled drug delivery can be used for vaccine delivery (112). Preparation of microparticles from water-insoluble polymers [e.g., poly(methyl methacrylate), poly(butyl cyanoacrylate), and poly(lactide-co-glycolide)] requires use of organic solvents or high temperature, both of which may not be good for maintaining tertiary structures of antigens. Preparation from water-soluble polymers frequently requires cross-linking reaction to make the polymers remain insoluble. It is possible that cross-linking agents cross-link not only polymer chains but also antigen molecules. Absorption of water into hydrophilic polymers results in swelling of the network, i.e., formation of hydrogels, or aquagels. Preparation of microparticles from hydrophilic polymers is preferred because it does not require organic solvents or high temperature. Polymers that have been used in the immunization vary depending on the route of administration.

For parenteral vaccination, biodegradable polymeric microparticles made of poly(lactide-co-glycolide) are commonly used as vaccine carriers. Poly(lactide-co-glycolide) has been well-characterized and known to be highly biocompatible. The size of microparticles can be easily controlled, and microparticles of less than 100 μm in diameter can be easily administered by injection through standard-sized needles (22 gauge or smaller). Because of the slow degradation of the polymer, antigens are slowly released from the microparticles for long term in much the same way as do alum adjuvants, and this results in enhanced immune responses. Other polymers, such as chitosan, have been used for preparation of vaccine formulations. Because one of the important roles that microparticles play in immunization is the slow release of antigens, a number of approaches have been tried to achieve antigen release at desired rates. The surface of microparticles can be modified to alter the adsorption and desorption kinetics of antigens. Alternatively, the pore size can be varied to control the release of antigens from microparticles.

The size of microparticles is known to play a critical role in oral immunization. In addition to protecting antigens from acidic and enzymatic degradation in the GI tract, microparticulates are known to enhance uptake by M-cells in the Peyer's patches, and the effectiveness of the uptake depends on the size of microparticles. It is generally thought that microparticles smaller than 10 μm

are preferentially absorbed by M-cells, and the smaller the size, the better the absorption. One study using microparticles of different sizes showed that the efficiency of uptake of 100-nm particles by the intestinal tissue was 15- to 250-fold higher than that of larger size microparticles (113). In addition to the small size, microparticles with more hydrophobic surface property are absorbed better than those with more hydrophilic surface property. There are, however, no definite studies confirming or supporting these assumptions. Once microparticles are placed in the GI tract, adsorption of numerous proteins and polysaccharides present in the GI tract would alter the surface chemistry drastically, and it is difficult to correlate a particular surface chemistry of the native microparticles with the absorption ability.

Virus-like particles (VLPs) consist of one or more viral-coat proteins. They are very immunogenic molecules that allow for covalent coupling of the epitopes of interest (114). Recently, parvovirus-like particles have been engineered to express foreign polypeptides in certain positions, resulting in the production of large quantities of highly immunogenic peptides, and to induce strong antibody, helper T-cell, and cytotoxic T-lymphocyte responses (114). Parenteral administration of recombinant VLPs of papillomavirus induced VLP-specific humoral and cellular immune responses (115). Immunization of VLPs without adjuvant via mucosal route is also known to elicit specific antibody at mucosal surfaces and also systemic VLP epitope-specific T-cell responses (115).

Liposomes are vesicles composed of naturally occurring or synthetic phospholipids. The bilayer structure can be single- or multicompartiment. The size can also vary from smaller than 1 μm to larger than 10 μm . When negatively charged lipid molecules, which form liposomes, interact with divalent cations, a solid, multilayered, crystalline structure called cochleate is formed. Because liposomes and cochleates can protect antigens from the GI tract and deliver them to the Peyer's patches, they have been exploited as an effective delivery system for oral vaccination.

Liposomes, like other vaccine-delivery systems, can exert immunoadjuvant effects. The surface charge of liposomes is known to affect the immune responses. Positively charged liposomes containing soluble antigens were reported to function as a more potent inducer of antigen-specific, cytotoxic T-lymphocyte responses and delayed-type hypersensitivity responses than negatively charged and neutral liposomes containing the same concentrations of antigens (116). Studies showed that the positively charged liposomes delivered proteinaceous antigens efficiently into the cytoplasm of the macrophages/antigen-presenting cells where the antigens are

processed to be presented by class I MHC molecules to induce the cell-mediated immune response (116).

Liposomes containing highly immunogenic glycoproteins of the Sendai virus on their surface, which are called fusogenic liposomes, showed enhanced antigen-specific humoral immunity in mice. The levels of antiovalbumin antibody were markedly increased in serum from mice immunized with OVA encapsulated in fusogenic liposomes. It appears that the fusogenic liposomes function as an immunoadjuvant in inducing antigen-specific antibody production (117).

Virosomes are liposomes containing viral fusion proteins that allow efficient entering into cells fusion with endosome membranes. Viral fusion proteins become activated in the low pH environment in the endosome to release its contents into the cytosol (118). Hepatitis A and influenza vaccines constructed on virosomes elicited fewer local adverse reactions than did their classic counterparts and displayed enhanced immunogenicity. Virosome-formulated influenza vaccine has also been shown to be safe and immunogenic when administered by the intranasal route (119). Other studies have suggested that immunopotentiating reconstituted influenza virosomes can be a suitable delivery system for synthetic peptide vaccines. The virosomes have a great potential for the design of combined vaccines targeted against multiple antigens and multiple pathogens (120).

Micelles are aggregates of detergent molecules in aqueous solution. Detergents are water-soluble, surface-active agents composed of a hydrophilic head group and a hydrophobic or lipophilic tail group. They can also align at aqueous/nonaqueous interfaces, reducing surface tension, increasing miscibility, and stabilizing emulsions. Polymeric micelles made of block copolymers, such as poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide), have been used as a delivery system for hydrophobic drugs. They can also encapsulate antigens for vaccination.

Niosomes are nonionic surfactant vesicles. They have been used to develop a vaccine-delivery system by peroral and oral routes. Ovalbumin was encapsulated in various lyophilized niosome preparations consisting of sucrose esters, cholesterol, and dicetyl phosphate. Encapsulation of ovalbumin into niosomes consisting of 70% stearate sucrose ester and 30% palmitate sucrose ester (40% mono-, 60% di/triester) resulted in a significant increase in antibody titers in serum, saliva, and intestinal washings (121).

Cross-linked protein crystals have been used as antigens. The immunogenicity of cross-linked protein crystals of human serum albumin was 6- to 30-fold higher in antibody titer than that of the soluble protein over an almost 6-month study (122). It is likely that the

cross-linked protein crystals release antigen in a slow-release manner, and in this sense, the cross-linked protein crystals function as a depot. The cross-linked protein crystals present high stability, purity, biodegradability, and ease of manufacturing, all of which are highly attractive features for vaccine formulation (122). Because the cross-linked protein crystals are microparticulates, they can also be used for vaccination through various routes.

IMMUNOMODULATION

Immunomodulation refers to treatments that alter immune responsiveness in a nonantigen-specific manner. Enhancement of the immune response is desired in the treatment of chronic infectious diseases and neoplastic diseases, whereas suppression is needed in cases of inappropriate or exaggerated immune response, including allergies and autoimmune diseases. There are numerous treatments that affect the activity of the immune system. The effect of currently available immunosuppressive drugs is very broad, giving these drugs undesirable side effects. The aim of the research in this area is to design treatments that selectively enhance or suppress immune responses. Some of the newer treatment options are those that target costimulatory molecules, and the use of CpG DNA, and cytokines.

Costimulation

Activation of T-cells requires two signals. The first signal is provided by recognition of MHC/peptide complex by the T-cell receptor. This does not result in proliferation and differentiation of the T-cell unless the T-cell receives a second, costimulatory signal. Several costimulatory signals have been identified, but the major costimulatory signal appears to result from the binding of CD28 on T-cells to B7 molecules on antigen-presenting cells. There are at least two B7 molecules, B7-1 (CD80) and B7-2 (CD86). Activation of antigen-presenting cells results in increased expression of B7-2, followed by B7-1. A second T-cell ligand of the B7 molecules is cytotoxic T lymphocyte antigen-4 (CTLA-4 or CD152) that, other than its name implies, is rapidly expressed on both CD4⁺ and CD8⁺ T-cells after binding of the T-cell receptor to the MHC/peptide complex on antigen-presenting cells. However, in contrast to the positive signal provided by CD28, CTLA-4 downregulates T-cell responses (123). CTLA-4 has a higher affinity for the B7-molecules than does CD28 and may prevent the activation of T-cells when B7 expression by dendritic cells is low and terminate

the immune response when its expression is strongly increased. A soluble chimeric protein, CTLA4Ig, blocks the binding of both CD28 and CTLA-4 to the B7 molecules and, thus, may prevent T-cell activation. Administration of this protein to patients with psoriasis vulgaris, an immune-mediated skin disease, in a phase I clinical trial resulted in significant improvement in approximately 50% of the patients (124). Selective inhibition of CTLA-4 with specific antibodies may boost the immune system. The combination of surgery and anti-CTLA-4 antibody therapy was highly effective in the prevention of metastatic recurrence in a mouse prostatic carcinoma model (125).

Other CD28 and B7 homologs continue to be identified and appear to play a role in costimulation (126). These molecules may provide additional targets for immunomodulation and suggest that it may be possible to fine-tune the immune response through pharmacologic intervention.

CpG DNA

Bacterial DNA has a higher content of the CpG dinucleotide than does vertebrate DNA, and, in contrast to vertebrate DNA, the CpG is not preferentially methylated. The unmethylated CpG DNA sequences provides a strong stimulus for the immune system (127). CpG DNA stimulates the secretion of IL-12 by macrophages and dendritic cells and thus provides a potent stimulus for type 1 immune responses. It also directly stimulates B cells to proliferate and differentiate into immunoglobulin secreting cells. A cellular receptor for CpG DNA has not been identified. The DNA appears to enter the cell via endocytosis, and some of the DNA escapes the endosomes into the cytoplasm of the cell where it activates various signaling pathways.

Applications for oligonucleotides containing unmethylated CpG sequences (CpG-ODN) are being explored in various areas of immunotherapy. Administration of CpG-ODN to mice protected against subsequent challenge with the intracellular bacteria *Listeria monocytogenes* and the intracellular protozoa *Leishmania major*. In addition, the CpG-ODN cured established *L. major* infections. The strong type 1 immunostimulatory property of CpG-ODN makes this compound a good candidate for vaccine adjuvants. Indeed, coadministration of CpG-ODN with antigen markedly boosts the humoral and cell-mediated immune responses. Allergic diseases such as asthma and atopic dermatitis are caused by type 2 immune responses directed against otherwise innocuous antigens. Treatment with CpG-ODN cleared established disease in a mouse model of airway hyper-reactivity, suggesting a CpG-induced reversal to type 1 immune

responses. CpG DNA may also have a place in immunotherapy of cancer because of its ability to activate NK cells through the induction of IL-12. Administration of CpG-ODN in combination with monoclonal antibodies directed against tumor antigens greatly enhanced the survival of mice that had been inoculated with tumor cells.

Cytokines

Cytokines play a critical role in the regulation of the immune and inflammatory response, and they are potential targets for therapy. Important limitations, however, are the pleiotropy and redundancy in the cytokine system and the short half-life and short action range of most cytokines. In spite of these limitations, considerable effort is spent on developing reagents that either block or enhance the activity of a specific cytokine.

Two remarkable successes of cytokine therapy are the treatment of multiple sclerosis with interferon- β and the treatment of rheumatoid arthritis and inflammatory bowel disease with tumor necrosis factor- α inhibitors.

Interferon- β

Clinical trials have demonstrated that subcutaneous injections of recombinant or natural interferon- β reduces the rate of exacerbation of relapsing-remitting multiple sclerosis (128, 129). The mode of action of interferon- β has not been determined. Interferon- β reduces the production of tumor necrosis factor- α and increases the secretion of IL-10 in vitro. TNF- α is a proinflammatory cytokine that may contribute to demyelination in multiple sclerosis. IL-10 suppresses macrophage function and the production of TNF- α . In addition, interferon- β may reduce the entry of leukocytes into the central nervous system, a critical component in the inflammation that causes the lesions in multiple sclerosis.

Tumor necrosis factor- α inhibitors

Tumor necrosis factor- α (TNF- α) is a cytokine with multiple biological effects. It is produced as a transmembrane precursor molecule by various cells in the body. It is cleaved by the TNF- α -converting enzyme and forms trimeric aggregates that bind to either the TNF-receptor (TNFR) I or the TNFR II that are expressed on many different types of cells. The extracellular domains of the TNFR can be cleaved by enzymes and can inhibit TNF- α activity by preventing binding of TNF- α to cell-bound receptors. Recent studies have demonstrated that inhibition of TNF- α activity resulted in significant improvement of the clinical condition of many patients with rheumatoid arthritis and inflammatory bowel disease (130, 131). These studies clearly demonstrate an important role of TNF- α in

rheumatoid arthritis and inflammatory bowel disease, although the precise mechanisms remain to be determined. The inhibition of TNF- α activity is achieved by treatment with anti-TNF- α monoclonal antibodies or with soluble TNFR-fusion protein. To reduce the induction of antibodies against the mouse monoclonal antibodies, the monoclonal antibodies are chimeric (i.e., the constant portion is derived from human immunoglobulins and the TNF- α -specific variable portion is derived from mice) or humanized (all of the immunoglobulin is human except for the complementarity determining regions that fold into the TNF- α -binding region). The TNFR-fusion protein is constructed from the extracellular domain of TNFRII and the Fc portion of human immunoglobulins. This construct has a much longer half-life than does the naturally occurring soluble TNFR.

CHALLENGES IN FUTURE VACCINE FORMULATIONS

Recent advancements in microbial pathogenesis, immunology, genetic engineering, plant genetics, and expression vector technology have formed the foundation for a new generation of vaccines and other pharmaceutical products. New developments in the delivery system have provided us with novel ways to enhance the immunogenicity of subunit antigens or nucleic acids by their controlled release and reduced degradation.

For more convenient and more effective immunization, current vaccine-delivery technologies need to be improved. Currently, vaccination of many inactivated or subunit antigens requires booster doses because of the lack of inherent immunogenicity found in the natural organism. Thus, reducing the number of doses is one of the primary goals in vaccination. Theoretically, various controlled-release technologies can be used to release antigens over time in a sustained or pulsatile manner and to direct antigens to specific antigen-presenting cells for increased vaccine efficacy. In addition to controlled-release technology, the single-shot vaccination requires development of better adjuvants. The mechanism of action of such adjuvants should be known so that reproducible results can be obtained in a mass vaccination program. The requirements and problems of immunizing immunocompromised, immature, older, or pregnant hosts need to be addressed effectively. Further improvement in our understanding of how to modulate Th1 and Th2 responses effectively would certainly help us design better vaccines. Another means of improvement is to combine a number of vaccines into multivalent vaccines. This will improve the

immunization compliance in people living in developed or developing countries. Because the majority of pathogens enter their hosts via mucosal routes, the new-generation vaccines should have the advantage of providing effective protection at the mucosal sites. An ideal vaccine would be one that provides life-long protection with a single inoculation. The new-generation vaccine formulations should also have high stability, thus avoiding the problems commonly observed during storage.

Validation of Analytical Procedures

Joachim Ermer

Aventis Pharma, Frankfurt am Main, Germany

John S. Landy

Aventis Pharma, Bridgewater, New Jersey, U.S.A.

INTRODUCTION

To the pharmaceutical world, the meaning of analytical methods validation is the process to confirm that a method does what it purports to do, that is, to document through laboratory studies that the measurement procedure can reliably assess the identity, strength, and/or quality of a bulk drug substance, excipient, or finished pharmaceutical product. To provide consistent, worldwide regulatory expectations, previously unavailable, the International Conference on Harmonization [ICH,^{[1]a}] has defined the methods validation process for the release and stability testing of all new products. This chapter interprets these ICH regulatory definitions and requirements,^[2,3] as well as provides direction toward rational and efficient validation.

Regulatory methods can be compendial or noncompendial. Wherever possible, methodologies are to be employed which are documented, generally recognized as official pharmacopoeia or compendia. Compendial methods are considered valid; however, suitability must be verified under actual conditions of use. Noncompendial methods require validation, and must be selected if a compendial method does not exist. A noncompendial method can be chosen over an existing compendial method, if it can be demonstrated to be superior to the compendial test.

Before a product dossier has been submitted to an agency for regulatory market approval, analytical laboratories have utilized validated methods to support toxicological, clinical, stability, development, scale-up, optimization, process, and cleaning validation studies. Unreliable data for any of these studies have the potential to completely undermine the speed and success of approval. A method's "life cycle"^[9] parallels the drug development process. Starting with early (preclinical) development projects, the related methods for drug substance and finished drug product require only some rudimentary validation to provide sufficient confidence in

the results, eventually leading to a complete methods validation package for the final stages of product development and commercialization (see "Validation During Drug Development and Manufacturing"). The methods life cycle concludes with methods transfers, monitoring of routine quality control (QC) usage, and revalidation. We define revalidation as repeating those parts of validation that are affected by a modification, for example, specificity, if the column has changed. Repeating the whole validation periodically is superfluous; instead, continuous monitoring of the performance of the analytical procedure should be performed (see "Maintenance of the Validation Status"). Many tests may be specified in the early development of a product or process that will not be ultimately selected for routine release testing. Clearly not all products reach the approved and marketing stage, due to toxicology, efficacy, or even business conditions. Multiple other changes can occur along the way toward approval such as active pharmaceutical ingredient (API, drug substance), synthetic route changes, drug product formulation, and process changes, as well as newly identified degradation pathways. All of these affect the method applied. Therefore, methods (development) validation requires efficient planning of resources to match the accuracy and precision requirements needed to assess product quality.

Methods Selection and Applicability for Routine Use

The target laboratory [development (R&D) or QC] where the methods will be utilized and the stage of development are just as important as the analyte/sample to be measured when considering the selection of a method as these will affect the accuracy and precision requirements, as well as laboratory economic, environmental, and ergonomic factors. Methods should be selected that are adequate for testing the attribute to be measured. They must be sufficiently selective, accurate, precise, and robust to demonstrate conformance to proposed specifications.

^a<http://www.ifpma.org/ich5q.html> (accessed March 2001).

It should be noted that a precise method is an extremely important attribute in QC. A precise method permits a fluctuation in the manufacturing process to be detected before it can cause an out-of-specification (OOS) event. With a sufficiently precise method, subsequent tightening of the specification should not necessitate modification or revalidation of the test method.

Additionally, these procedures should be devised with the explicit objective of transferring the methods to a qualified laboratory. The development laboratory should specify test techniques, parameters, and other details in the final dossier submission that have the highest likelihood of being transferred successfully to a QC site. Methods shall be selected that experience shows will likely be reproducible. Reproducibility is assessed late in the validation process. Methods should be designed to minimize direct analysis and turnaround time, to maximize efficiency, and to shake the convenience, safety, health and environmental impacts of the test as consistent with the other primary objectives of method development. Development considerations should include equipment and expertise limitations of the receiving laboratory, expected sample volumes, and achieving a balance between acceptable traditional validation parameter values (accuracy, precision, etc.) and analysis time and robustness. The receiving laboratory should participate in the early review of these methods to provide and prepare for the transfer (e.g., purchase equipment, obtain reference standard supply) and should also assess safety, meaningful system suitability parameters (derived from robustness studies), and overall clarity of the written method. Automated tests may be desirable. Where a method has been developed and performed on automated equipment, an early assessment should be made as to whether automation is critical to the accuracy, precision, reproducibility, and robustness of the method compared to a manual method.

Validations and Specifications (Limits)

Method validations and drug substance or finished pharmaceutical product specifications are intimately linked. To ensure transferability of the method and to ensure the method will operate successfully in a QC site, the method variation (from the intermediate precision) should be known and monitored. The method variation is an estimate of the variation that will be experienced in routine use of the method. More method variation will create unacceptable random failure rates, and provide no room for reasonable product variation or even minor stability changes. The method variation should be less than one-third of the interval from the mean or target (typically

the midpoint of the upper and lower specification limit) value to the nearest specification limit, or one-sixth of the in-specification operating range of the method, whichever is smaller. Otherwise, OOS results may occur, even for product that was produced at target and with zero process variation.

If a reasonable opportunity exists (based on common belief and experience) to improve the method variation to one-fourth or preferably less of the specification interval, this effort should be made. In the example of a drug product where the specification is 95%–105% with a target of 100%, then the maximum method variation must be less than 1.67%; however, if the method variation is above 1.25%, efforts should be made to reduce its variation. Ideally, the method variation should not be greater than 2.0% even if the specification range is wider than 10%. The 2.0% maximum method variation requirement does not apply to tests where the variation of the method is substantially confounded with variation of the product being measured.

Validation as a Good Business Practice

While compliance to legal requirements is paramount to the pharmaceutical industry and its associated regulatory bodies, it is by far not the only reason to judiciously develop and validate analytical procedures. Well-developed and validated methods represent good business practices, as haphazardly chosen and/or poorly validated methods can haunt a company financially for the short and long term.

Extensive sample preparation with long cycle times, and excessive hazardous solvents usage and disposal are easily calculable financial and safety losses. Imprecise stability data can easily lead to erroneous or shortened expiration dating assignments. Poorly validated methods increase the chances of OOS results and investigations absorb costly laboratory resources. Incapable methods (inadequate precision for the associated specification) cannot readily discriminate passing from failing products: therefore, one can release unacceptable product, leading to product recalls. Inaccurate methods can lead to sub- or superpotent products. Nonreproducible methods do not transfer quickly or efficiently and can become limiting factors of pre-approval inspections with potential to affect product launches.

REGULATORY REQUIREMENTS

Due to the importance of demonstrating the suitability of new analytical procedures described in submission dossiers, in the 1980s many regulatory agencies published

requirements for analytical validation, in varying details. The U.S. Food and Drug Administration (FDA) issued two guidelines, one for the applicant,^[10] the other for inspectors and reviewers.^[11] The first one is also intended to ensure that the analytical procedure can be applied in an FDA laboratory and requires, therefore, a detailed description of the procedure, reference materials, discussion of potential impurities, etc. With respect to validation, data should be provided to demonstrate an appropriate accuracy, precision, linearity, selectivity, and quantitation limit (QL) for impurities and degradation products. For drug product, recovery, lack of interference from placebo, and variability with respect to time, laboratory, operator, and column should be demonstrated.

The second guideline is focused on reversed-phase chromatography and gives details regarding critical methodological issues, as well as acceptable results for parameters. A revised draft for the first guideline, published in 2000,^{[12]b} focused on providing raw data in detail. However, this has nothing to do with validation and should be an inspection issue, as there is a real danger to burden the validation documentation with huge amounts of data, which make it difficult to concentrate on a scientifically justified demonstration of suitability. Additionally, there are some inconsistencies with the ICH documents, which are not helpful for the harmonization process.

The same validation characteristics were described in the *U.S. Pharmacopoeia (USP)*.^[13] Three categories of analytical procedures were distinguished: quantitation procedures for main components in drug products, procedures for determination of impurities, and procedures for pharmaceutical–technical characteristics (e.g., dissolution). The guidance on validation of the European Community^[14] was rather general and incorporated in the respective sections of the submission documentation. In the Canadian guideline,^[15] a very detailed discussion is provided for requirements and especially acceptance criteria. Although this gives some orientation, the given acceptance criteria were sometimes a bit ambiguous, for example, the intermediate precision/reproducibility of below 1% for drug substances.

International Conference on the Harmonization of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH)

This process was initiated in 1990 in order to harmonize the submission requirements for new pharmaceuticals in

the three main regions of Europe, the United States, and Japan and to avoid duplication, inefficiencies, and delays. A forum was created for a constructive dialogue between regulatory authorities and industry. The six cosponsors of ICH were the European Commission, the European Federation of Pharmaceutical Industry Association (EFPIA), the Japanese Ministry of Health (MHW), the Japanese Pharmaceutical Manufacturers Association (JPMA), the Food and Drug Association (FDA), and the Pharmaceutical Research and Manufacturers of America (PhRMA). Several organizations such as the Canadian Health Protection Branch (HPB), the USP, and the European Pharmacopoeia (EP) participated as observers. Within the Quality section, seven topics were taken into account:^[1] stability, validation,^[2,3] impurities,^[4–6] pharmacopoeial harmonization, biotechnological products, specifications,^[7,8] and good manufacturing practice (GMP).

The ICH was very valuable in harmonizing terms and definitions^[2] as well as basic requirements^[3] for analytical validation. Of course, due to the nature of the harmonization process, there are some compromises and inconsistencies, but the importance of a proper validation is currently widely known and accepted. In Table 1, the required validation characteristics for the various types of analytical procedures are shown. In the following, the main ICH requirements for the validation characteristics are summarized. However, the ICH guidelines must not be regarded as a checklist. “It is the responsibility of the applicant to choose the validation procedure and protocol most suitable for their product”.^[2]

Specificity

“Specificity is the ability to assess unequivocally the analyte in the presence of components which may be expected to be present. Typically, these might include impurities, degradants, matrix, etc.”.^[2] For identification, discrimination between closely related compounds likely to be present should be demonstrated by positive and negative samples. For assay and impurity tests, available impurities/degradants can be spiked to the corresponding matrix or degraded samples can be used. Specificity can also be demonstrated by verification of the result with an independent analytical procedure. The overall specificity can (and often will) be obtained by a combination of several analytical procedures, for example, in case of a partly specific titration with a chromatographic impurity determination. In case of chromatographic separations, resolution factors should be obtained for critical separations. Tests for peak homogeneity, for example, by diode array detection (DAD) or mass spectrometry (MS)

^b Lack of specificity of one analytical procedure could be compensated by other supporting analytical procedure(s).

^c Reproducibility not needed for submission.

^d May be needed in some cases.

(From Refs. 2, 3).

are recommended. All tested substances should be documented including the rationale of their selection. All relevant results, e.g., as tables or chromatograms, should be provided, discussed, and evaluated.

Linearity

“The linearity of an analytical procedure is its ability (within a given range) to obtain test results which are directly proportional to the concentration (amount) of analyte in the sample”.^[2] It can be distinguished between the linearity of the detector/instrument, obtained from a dilution of the analyte and the linearity of the analytical procedure, obtained from independent preparations (spiking, weighing) including (as far as possible) the complete sample pretreatment. At least five concentrations over the whole working range should be analyzed. Besides a visual evaluation of the analyte signal as a function of the concentration, appropriate statistical calculations are recommended, such as a linear regression. The parameters slope and intercept, the sum of squares, and the coefficient of correlation should be reported.

Range

“The range of an analytical procedure is the interval between the upper and lower concentration (amounts) of analyte in the sample (including these concentrations) for which it

has been demonstrated that the analytical procedure has a suitable level of precision, accuracy and linearity”.^[2]

The following minimum ranges are required:

- Assay: 80–120% of the test concentration.
- Content uniformity: 70–130% of the test concentration.
- Dissolution: 20% below to 20% above the specified range.
- Impurities: reporting level to 120% of the specification.
- 100% method: reporting level of the impurity to 120% assay specification.

Accuracy

“The accuracy of an analytical procedure expresses the closeness of agreement between the value which is accepted either as a conventional true value or an accepted reference value and the value found”.^[2]

This validation characteristic is an indication of systematic errors (bias). Accuracy can be demonstrated by the following procedures:

- Inferred from precision, linearity, and specificity.
- Comparison of the results with those of a well characterized procedure.
- Application to a reference material (drug substance).
- Recovery of drug substance added to placebo (drug product).

- Recovery of the impurity added to drug substance or drug product (impurities).

For the quantitative approaches, at least nine determinations across the specified range should be obtained, for example, three determinations at three concentration levels. The percent recovery or the difference between the mean and the accepted true value together with the confidence intervals (CIs) are recommended.

Precision

“The precision of an analytical procedure expresses the closeness of agreement (degree of scatter) between a series of measurements obtained from multiple sampling of the same homogeneous sample under the prescribed conditions. Precision may be considered at three levels: repeatability, intermediate precision, and reproducibility”.^[2] Precision measures random errors and should be obtained preferably with authentic samples. As parameters, the standard deviation, the relative standard deviation (RSD) (coefficient of variation), and the CIs should be calculated for each level of precision. Repeatability reflects the analytical variability under the same operating conditions over a short interval of time (within-assay, intra-assay). At least nine determinations across the specified range or six determinations at 100% test concentration should be performed. Intermediate precision includes the influence of additional random effects according to the intended use of the procedure, i.e., within laboratories variations, for example, different days, analysts, equipment, etc. Reproducibility, i.e., the precision between laboratories, is not required for submission, but can be taken into account for standardization of analytical procedures. The variations should be selected according to the intended use of the analytical procedure.

Detection and quantitation limit

“The detection limit (DL) of an individual analytical procedure is the lowest amount of analyte in a sample which can be detected but not necessarily quantified as an exact value. “The QL of an individual analytical procedure is the lowest concentration of analyte in a sample which can be quantitatively determined with suitable precision and accuracy”.^[2]

Various approaches can be applied:

- Visual definition.
- Calculation from the signal-to-noise ratio (DL and QL correspond to the 3- or 2- and 10-fold of the noise level, respectively).

- Calculation from the standard deviation of the blank (Eq. 1).
- Calculation from the calibration line at low concentrations (Eq. 1).

$$DL; QL = \frac{F \times SD}{b} \quad (1)$$

where F is the factor of 3.3 (DL) or 10 (QL); SD is the standard deviation of the blank, standard deviation of the ordinate intercept, or residual standard of the linear regression; and b is the slope of the regression line.

The estimated limits should be verified by analyzing a suitable number of samples containing the analyte at the corresponding concentrations. DL or QL and the procedure used for determination as well as relevant chromatograms should be reported.

Robustness

“The robustness of an analytical procedure is a measure of its capacity to remain unaffected by small, but deliberate variations in method parameters and provides an indication of its reliability during normal usage”.^[2] During the development phase of the analytical procedure, susceptible parameters should be identified, for example, stability of analytical solutions, extraction time, pH and composition of mobile phase, column lots and suppliers, temperature, flow rate, etc. A factorial design is encouraged.

System suitability tests

“System suitability testing is an integral part of many analytical procedures ...”.^[3] Suitable parameters depend on the type of analytical procedure; reference is given to pharmacopeias.

RATIONAL AND EFFICIENT VALIDATION

As analytical procedures are used throughout drug development and the manufacturing and release of drug substances and drug products, the reliability of their results is essential. Important decisions such as the establishment of the shelf-life from stability studies, the need for additional toxicological trials if new impurities appear or if known impurities exceed the qualified levels, and the reworking of batches and batch release or rejection are based on analytical results. Therefore, an appropriate validation to demonstrate the performance and suitability

of the analytical procedures is much more than a formal requirement.

Suitability of the Analytical Procedure

What does “suitability for its intended purpose” mean? Basically, suitability is determined by the specification limits (or the aim of the analytical investigation) and the design of the given test item. For some applications, the requirements are explicitly defined in the ICH guidelines. For example, the reporting level for unknown impurities in drug substances is set to 0.05% or 0.03%;^[4] thus the corresponding test procedure must be able to quantify impurities at this concentration with an appropriate level of precision and accuracy. A maximum permitted analytical variability can be calculated from assay specification limits^[16] (see Fig. 1 and Eq. 2), based on the concept of CIs to describe analytical and manufacturing variability.^[17] At least, the compatibility between specification limits and analytical variability should be verified. Preferably, the limits are established taking the analytical and manufacturing variability into account. In this case, an analytical variability normally expected for the given kind of analytical procedure (analytical state of the art) can be defined as acceptance criterion. Of course, the thus-obtained limits must primarily meet necessary quality and safety requirements. However, if this is satisfied, limits can reflect analytical variability.^[7,8] With respect to

assay determinations, the variability of the analytical procedure is often larger than the variability of the manufacturing.

$$s_{\max} = \frac{|(BL - SL)|\sqrt{n}}{t_{n-1,0.95}} \quad (2)$$

where BL is the basic limit, obtained from the theoretical content and the manufacturing variability, with respect to the critical “half” of the specification range; SL is the (overall) specification limit with respect to the critical “half” of the specification range; n is the number of repetitions in the assay; t is the Student’s t -factor for $(n - 1)$ degrees of freedom in the validation and 95% statistical confidence (one-sided).

It must also be demonstrated that the design of the analytical procedure, for example, the intended calibration mode, the number of repetitions, etc. is suitable. Therefore, suitability is strongly connected with the given, individual analytical procedure. The performance parameters are of varying importance and have different acceptance criteria. In consequence, a “checklist” approach to validation must be avoided. The analyst has to identify critical parameters, which are of importance for the required performance of the individual analytical procedure, to design the experimental studies accordingly and to define acceptance criteria for the results.

Statistical tests should only be carefully (directly) applied as acceptance criteria due to the small number of data normally obtained. Sometimes, because of abnormally small variabilities in the analytical series, differences are identified as significant which are of no practical relevance.^[18] In addition, when comparing independent methods for the proof of accuracy, different specificities can be expected which add a systematic bias, thus increasing the risk of the aforementioned danger. The analyst must decide whether detected statistical differences are of practical relevance. On the other hand, a large variability can also obscure differences which are not acceptable. If validation software is used, it must be flexible enough to meet these precautions.^{[19]c}

The analytical state of the art should be taken into account, although it is not the ultimate goal to optimize an individual analytical procedure as well as possible. It is also very important to recognize that the release of a given batch is based on a whole set of test procedures which complement and supplement each other. Their selection in the specification design^[7,8] has, therefore, considerable influence on the required performance of the individual control test and, hence, on its validation.

Fig. 1 Construction of specification limits from 95% CIs of the probability distribution of experimental results. The procedure is shown for the lower limits. BL = basic limits, imposed by the variability of the manufacturing process. SL = overall specification limit, combination of BL and the (lower) limit of the one-sided 95% confidence interval of the analytical variability. (From Ref. 16.)

Validation Characteristics

Specificity

There has been some controversy regarding the technical term for this validation characteristic, i.e., specificity vs. selectivity.^[20] This may be partly attributed to the fact that in contrast to an isolated test procedure in analytical chemistry, in pharmaceutical analysis, the sum of various control tests and hence their combined specificity is used for the overall evaluation.

In spite of all discussions, there is a broad agreement that this validation characteristic is of crucial importance and builds the critical basis for each analytical procedure. As no absolute and quantitative measure exists (at least for the overall specificity), the requirements depend on the individual analytical procedure as well as on its combination with others.

Chromatographic Separation. With respect to chromatographic techniques, specificity can be demonstrated by a sufficient separation of the substances present. For the assay, appropriate separation means an adequate resolution between the peak of interest and other peaks (e.g., impurities, placebo or matrix components), which need not to be separated from each other. In contrast, universal procedures for the determination of impurities require a sufficient separation of all relevant impurity peaks. The required resolution is strongly dependent on the difference in the size of the corresponding peaks as well as on their elution order.^[21] Therefore, if separation factors are determined, the typical concentration levels or the specification limits (as worst case) of the impurities should be maintained. Resolution factors can be calculated according to EP (Eq. 3) and USP (Eq. 4) at half height and at the baseline, respectively. However, this is only sensible for baseline-separated peaks. The USP approach is less sensitive toward tailing, but more complex to determine.

$$R_s = \frac{1.18(t_{Rb} - t_{Ra})}{w_{0.5a} + w_{0.5b}} \quad (3)$$

$$R_s = \frac{2(t_{Rb} - t_{Ra})}{w_a + w_b} \quad (4)$$

where $t_{Ra,b}$ is the retention time of peaks a and b with $t_{Rb} > t_{Ra}$, $w_{0.5a,b}$ is the peak width a and b at half height, and $w_{a,b}$ is the peak width a and b at baseline.

In case of incomplete separations, especially for peaks of different magnitude, calculations according to Eqs. 3 and 4 are not possible or are biased due to the additivity of the peak curves. Here, other separation parameters such as

the peak-to-valley ratio (p/v) should be used.^[23] This approach, which measures the height above the extrapolated baseline at the lowest point of the curve separating the peaks with respect to the height of the minor (impurity) peak (Fig. 2), is directly related to the peak integration and independent on tailing or “smearing” effects in the elution range behind the main peak.^[22,23]

Besides a “physical” improvement of the separation, it can also be optimized “visually” if the spectra of the two concerning peaks are different. Then, a suitable wavelength can be selected to suppress interferences. However, such an approach has to be balanced with respect to the QL and the robustness of the quantitation if the detection wavelength does not correspond to a stable region of the spectra, such as (relative) maxima or minima or shoulders.

Peak Purity Investigations. In order to be able to detect the coelution of unknown substances, peak homogeneity (also termed peak purity) investigations should be performed.

In case of not too large concentrations differences of the coeluting peaks, simple methods of one-dimensional detection can be applied. For normal eluting pure substances, the peak width at half height is proportional to the retention time. Therefore, performing isocratic chromatography with different concentrations of organic modifier, a plot of the peak width vs. the retention time will give a linear relationship for homogeneous peaks. For a single chromatographic separation, the symmetry factor is independent on the height of pure substance peaks.^[24]

In case of small amounts of coeluting impurities, rechromatography of suspected peaks represents a simple, universally available and sensitive approach. The more the two applied chromatographic methods differ, the

Fig. 2 Peak separation indices: peak-to-valley ratio $p/v = a/b$. If the calculation is modified as $p/v = 1 - b/a$, the parameter is normalized and has the same sense as the resolution factor, i.e., increasing values indicate better separation, with a maximum of 1.

greater is the power of the investigation. Various combinations can be taken into consideration such as coupling of reversed phase (RP) chromatography with another RP method (different eluent, pH, column), size exclusion chromatography, ion chromatography, thin layer chromatography (TLC), capillary electrophoresis (CE),^[25] gas chromatography (GC), etc. The rechromatography can be performed off-line with isolated peak fractions, or as a direct orthogonal coupling of the two methods. Working with isolated peak fractions, care should be taken to avoid artifacts due to degradation.

With diode array detectors or scanning detectors, the spectral peak homogeneity can be investigated.^[26] However, such an approach requires a difference in both the spectra and in the retention time of the coeluting substances. If this is fulfilled, detection of inhomogeneities with commercially available software is easy, if the concentration difference is not too large (Fig. 3b). However, impurities below 1% are difficult to recognize (Fig. 3c).

The most discriminating technique for investigation of the peak purity is mass spectrometric detection.^[27,28] Using on-line LC-MS coupling, mass spectra are taken over the whole elution range of the suspected peak (Fig. 4). In a first step, the obtained signals (mass-to-charge ratio, m/z) must be assigned to the main substance. In the given example, m/z 275.8 and 295.6 belong to the drug substance (Fig. 4, inset B) and represent the doubly charged molecular ion and a cluster formed by the doubly charged ion and acetonitrile (from the eluent). If during the spectra "scrolling" additional masses are detected such as m/z 324.9 (Fig. 4, inset A), the corresponding mass chromatogram is extracted. Differences in the retention time or elution behavior with respect to the UV peak is proof of a coeluting impurity. Even peaks with identical retention can be attributed to impurities if a

change in the mass-to-charge ratio cannot be explained by the drug substance itself. In the given example, the impurity amounts to 0.5%. Of course, the DL depends on the individual MS response of the concerned substances and diastereomers cannot be detected. If LC procedures with nonvolatile buffers are validated, the corresponding peak fractions can be isolated and rechromatographed under MS-compatible conditions. Alternatively, the coupling can be performed on-line.^[29] Although not often applied in routine (pharmaceutical) analysis, MS detection offers tremendous gains in efficiency and reliability of the procedures, such as highly specific detection (largely) without interferences, for monitoring of impurity profiles and identification.^[28]

If samples from stress testing are used to demonstrate appropriate separation power, care should be taken to avoid overdegradation as this would result in secondary (or even higher order) degradants which are of no practical relevance. Therefore, degradation should be restricted to about 10%. Alternatively, samples from regular stability studies (accelerated storage conditions) may be used.

Linearity and range

Although a linear relationship between the analyte concentration and the measured signal will exist for most methods used in pharmaceutical analysis, there are some exceptions such as TLC and fluorescence detection. Therefore, the term "analytical response" would be more appropriate.

Prerequisites for the Calibration Types. It depends on the design of the analytical procedure as to which regression parameters are meaningful and which results are acceptable. In other words, the model to be used for

Fig. 3 Investigation of chromatographic peak purity by diode array detection: (a) spectra of drug substance and impurity; (b) coelution of a mixture containing about 10% impurity; (c) coelution of a mixture containing about 0.5% impurity. The spectra were obtained in the peak maximum, at about 5% and 50% of each side of the peak. The normalization was performed with respect to the first spectrum at the peak front (a matchfactor of 1000 means identical spectra) using commercial software.

Fig. 4 Investigation of chromatographic peak purity by means of LC-MS. The top and bottom trace show the UV chromatogram at 240 nm and the extracted ion chromatogram for a mass-to-charge ratio (m/z) 325. Insets A and B display (two of the) mass spectra taken at different retention time ranges of the UV-peak. Optimizing the chromatographic conditions resulted in a separation of the impurity which amounts to 0.5% area at 240 nm (data not shown).

quantitation must be justified. For a single-point calibration (external standardization), a linear function, zero intercept, and the homogeneity of variances are required. The prerequisites for a linear multiple-point calibration are a linear function and in case of an unweighted calibration also the homogeneity of variances. A nonlinear calibration requires only a continuous function. With respect to the 100% method (area normalization for impurities), both for the main peak and the impurities, a linear function and a zero intercept are required, within their working ranges.

The required linearity range must be obtained from the working range of the analytical procedure. It may be useful to extend the minimum concentration range when applying a single-point calibration in order to avoid an extensive extrapolation to zero. This might cause problems in the evaluation of the significance of the intercept. If the calibration for an analyte determination in a complex matrix (drug product, impurities, and degradants by external standards) or with a complex sample preparation is intended to be performed with a simple solution of the reference standard, this linearity should be compared with the linearity of the whole procedure using reconstituted (spiked) samples.

The homogeneity of variances over the whole range (homoscedasticity) is a prerequisite for an unweighted linear regression in order to ensure the same influence of all concentrations (Fig. 5). This can be verified by performing a suitable number of repeated measurements ($n = 6-10$) at the minimum and the maximum of the required linear range, and comparing the variances with an F -test. However, in pharmaceutical analyses, as the concentration range of interest is usually not very large, it is not required to perform a separate test for the homogeneity of variances. In general, the homogeneity of variances is maintained over about two orders of magnitude when using UV absorbance (within the linear range of the detector/instrument). If a calibration is extended over several orders of magnitude (which is more common for bioanalysis, but may also be considered for impurity determinations), variances are not likely to be homogeneous. As an unweighted linear regression minimizes the absolute residual sum of squares, higher concentrations with larger absolute scattering dominate (Fig. 5a) and are better fitted to the regression line. Consequently, large deviations will occur if such a regression line is used for quantitation of small concentrations (Fig. 5b). For a better

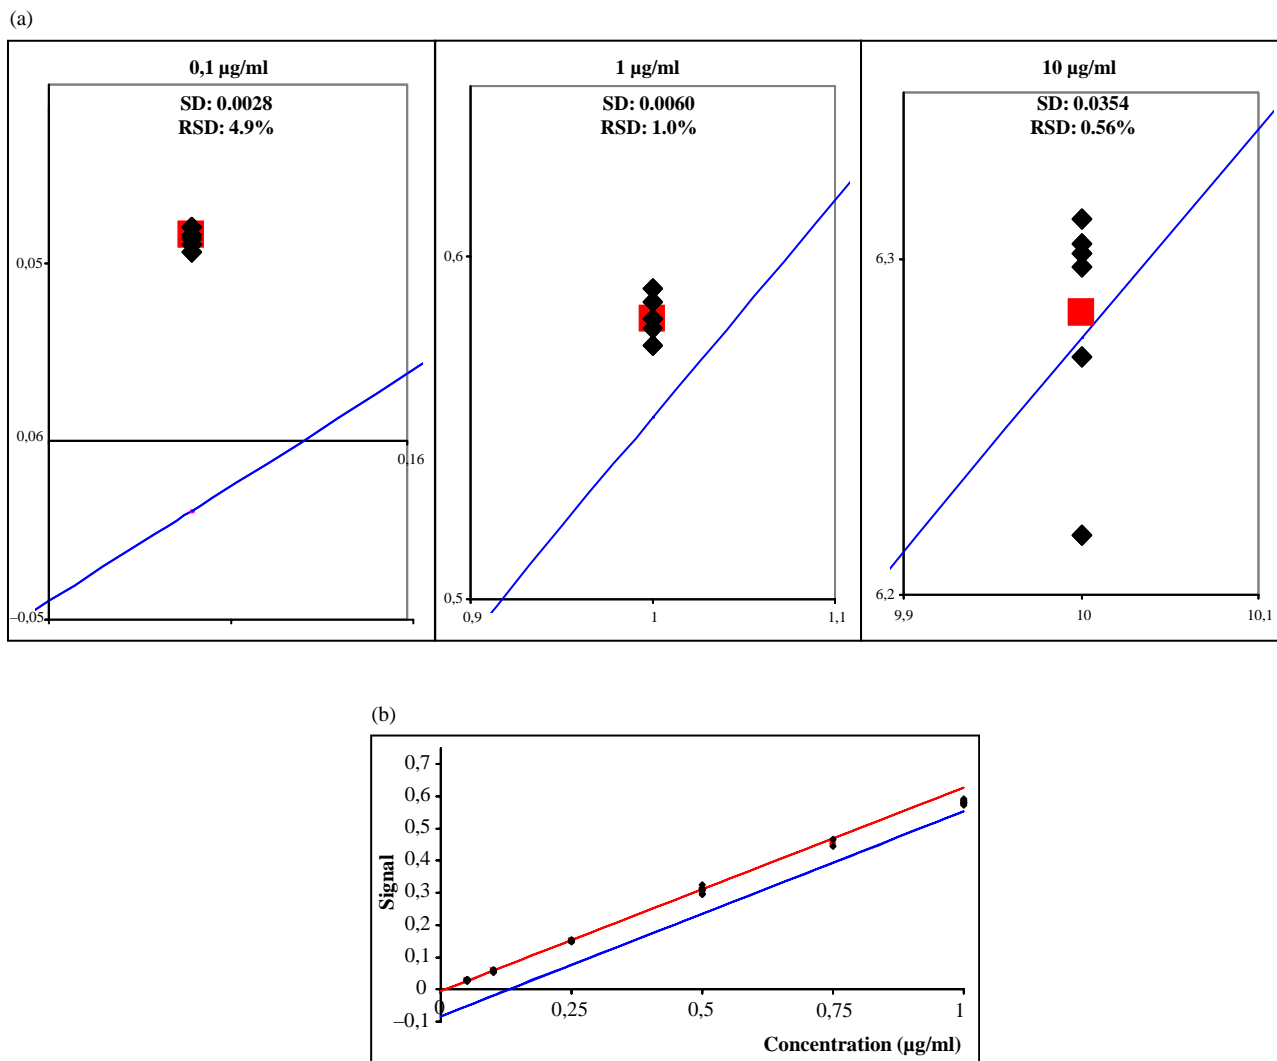

Fig. 5 Dependence of the variability on the analyte concentration (a) and its influence on the regression line (b). (a) Three concentration levels with dispersion parameters, calculated from six determinations each. The same scaling with respect to the signal axis is used. Whereas the absolute standard deviation decreases about 14-fold over three orders of concentration magnitude, the RSD increases considerably. The line obtained by unweighted linear regression of experimental data ranging from 0.05 µg/ml to 100 µg/ml is shown in blue. (b) The lines obtained from weighted (red line, weighting factor $1/x$ and unweighted (blue line) linear regression from 0.05 µg/ml to 100 µg/ml are shown in the lower concentration range.

representation of the lower concentrations, additional weight must be given to their signals performing a weighted linear regression. As weighting factors, the reciprocals of the individual standard deviations or variances can be used or, as an approximation the reciprocals of the concentrations themselves or of their squares. The equations can be found in statistical textbooks or in corresponding software products.

If deviations from linearity are detected or known, nonlinear response functions must be applied, for example, quadratic regressions. However, these models should be

used carefully if a linear relationship is normally assumed for the analytical procedure. Otherwise, it would also fit erroneous experimental values due to the larger flexibility of the regression curve. According to the principle of Ockham's blade, the model should be kept as simple as possible. Even in the case of intrinsic nonlinear response functions, it can be investigated if deviations resulting from linear regression are acceptable in the required working range. In the example given in Fig. 6, the difference between the results obtained by the quadratic regression and a linear regression from 400 ng to 700 ng

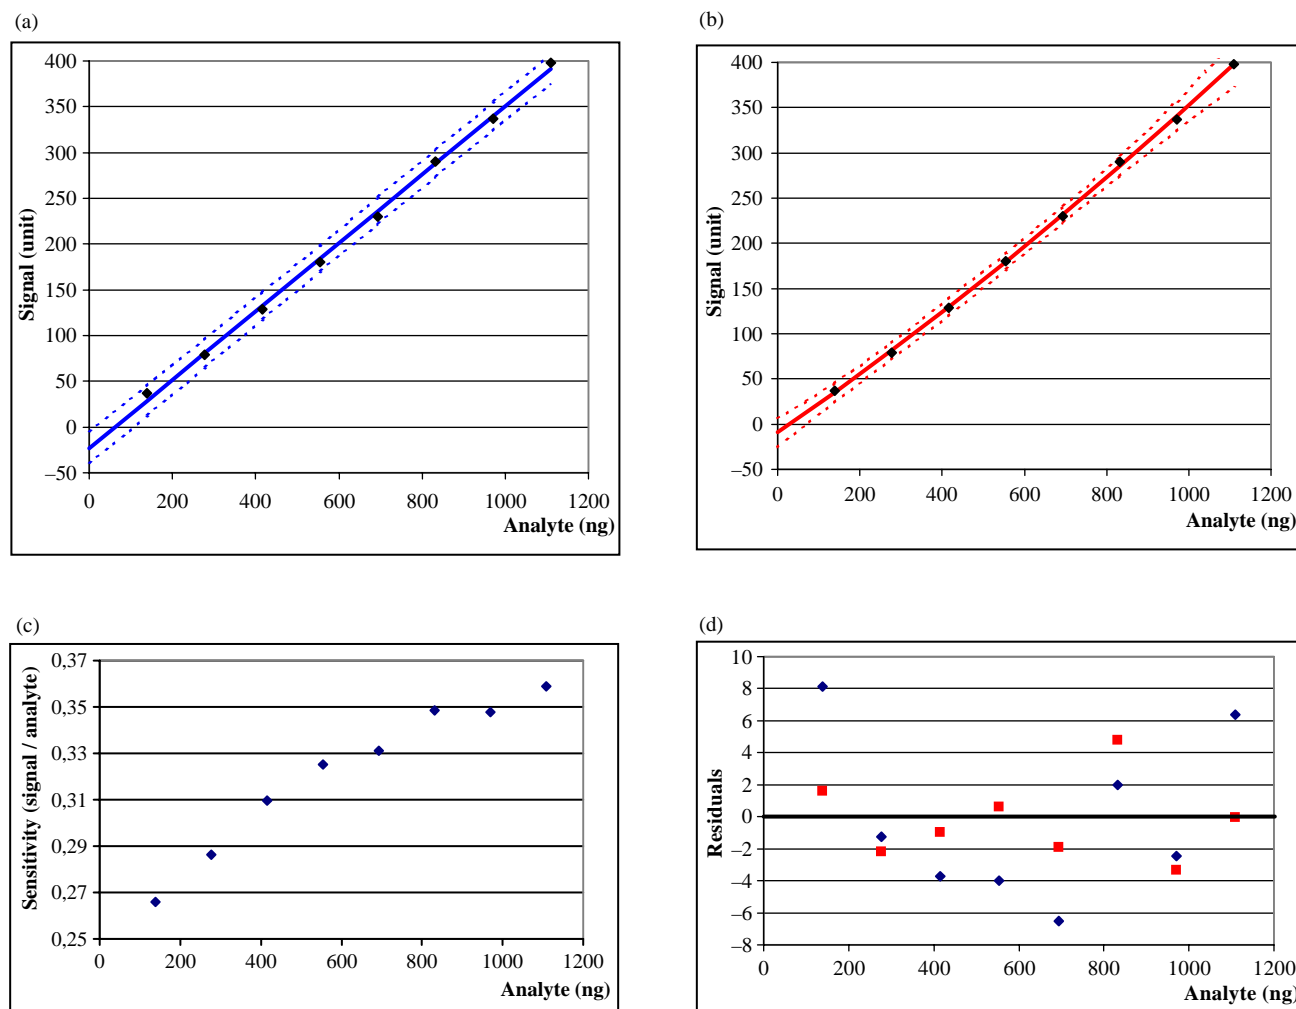

Fig. 6 Deviation from a linear response function. The experimental data were obtained by an LC procedure with nitrogen detection. (a) Unweighted linear regression ($y = a + bx$). The regression line and the limits of the 95% prediction interval are shown. The following parameters were calculated: slope with 95% CIs: 0.374 ± 0.015 ; intercept with 95% CIs: -23.09 ± 10.72 ; residual sum of squares: 189.68; residual SD: 5.62; relation standard error of slope: 2.41%; RSD of sensitivities: 10.12%; coefficient of correlation: 0.99916. (b) Quadratic regression ($y = a + bx + cx^2$). The regression line and the limits of the 95% prediction interval are shown. The following parameters were calculated: coefficient a : -9.217 ; coefficient b : 0.314; coefficient c with 95% CIs: $0.000048\% \pm 65.04\%$; residual sum of squares: 45.965; residual SD: 3.032. (c) Sensitivity plot (ratio of signal to analyte vs. analyte). (d) Residuen plot (difference of experimental to calculated signals vs. analyte) for the unweighted linear regression (blue) and the quadratic regression (red).

analyte (to represent a multiple-point linear calibration) is calculated to 0.4% and 0.55% at the lower and upper limit of the range, respectively. This must be evaluated with respect to a precision of about 2% for this type of procedure.

Evaluation of Linearity. In the ICH guideline, there are only scarce hints how to evaluate linearity. Primarily, a qualitative statement is sufficient for the evaluation of linearity (linear function): Does a linear relationship exist

in the required working range? When aiming at a single-point calibration, a positive answer is sufficient (in addition to a zero intercept) because the regression parameters obtained during validation are not used further in routine testing. In pharmaceutical analysis, this is also the case using a multiple-point calibration. However, relevant parameters may be selected to define acceptance limits for a system suitability test in routine calibration.

The coefficient of correlation is generally expected (and also mentioned in the ICH guideline), but it is not a

quantitative measure for the degree of linearity. It just gives an indication of whether a relationship exists between two sets of data.^[30] This is illustrated in Fig. 6. The coefficient of correlation for a linear regression shown in Fig. 6a was calculated as 0.99916. However, the more narrow 95% prediction interval of the quadratic regression (Fig. 6b) as a measure for the expected deviation of (future) experimental data from the regression line indicates a deviation from linearity. This is also easily recognized by investigation of the sensitivities, i.e., the ratio of analytical signal and the corresponding concentration (Fig. 6c). Their graphical presentation as a function of the concentration results in a horizontal line for the linear range of the procedure (Fig. 7). The ASTM^[31] recommends an interval of $\pm 5\%$ around the sensitivity mean. This interval should be adjusted to the concentration range in question; an acceptable precision can be used for orientation purposes. For concentrations around the QL, a wider interval can be accepted than for an assay procedure (e.g., $\pm 2\%$). Plotting the differences between the experimental values and the values calculated using the regression function vs. the concentration (residual plot, scatterplot) is another possibility of graphical linearity evaluation. With the proper response function, the residuals display a random (and narrower) scattering around the zero line; otherwise a systematic pattern is observed (Fig. 6d). However, in case of only few data (e.g., five according to ICH), a systematic pattern might be difficult to recognize. Here, the sensitivity plot is preferable as trends are better detectable as an upward or downward sloping of the data points.

Fig. 7 Sensitivity plot (ratio of signal to analyte vs. analyte) for an LC-assay procedure with UV detection. The means (blue) and the individual (red) sensitivity values, the average sensitivity (solid line) and the $\pm 2\%$ limits (dotted lines) are displayed. The larger scattering for the lower concentrations is caused by their larger influence (weight) on the ratio, compared with larger concentrations.

The standard error of slope is a suitable numerical parameter for the evaluation of linearity. It measures the deviation of the experimental values from the regression line and thus represents a performance parameter with respect to the precision of the regression. Expressed in percent (relative standard error of slope), it is comparable to the RSD obtained in precision studies in the given concentration range (e.g., 10%–20% RSD at the QL, 1%–2% for assay). Therefore, this parameter is better suited for evaluation purposes than the residual sum of squares and the residual standard deviation, which are also measures of the deviation between the experimental data and the regression, but they depend on the absolute magnitude of the signal values and are difficult to compare with results from other equipment or with other procedures.

As statistically based linearity test, the significance of the quadratic coefficient can be checked (see Fig. 6b). If the CI of the quadratic coefficient c ($y = a + bx + cx^2$) includes zero, the quadratic term becomes zero and the equation is reduced to a linear function. However, if a statistical difference is obtained, their practical relevance should be evaluated. For example, if the data display a very small scattering, combined with a slight trend, a quadratic regression could result in a (statistically) better fit. But this does not justify the use of the more complex model, if the difference between the results of the two regression models is negligible in the working range compared with the expected precision (e.g., 0.1% maximum deviation and 1.4% RSD at the working concentration).

Evaluation of the Intercept. The occurrence of (non-negligible) ordinate intercept is an indication of systematic errors, as it can be seen in Fig. 6a. If there are no matrix effects, adsorption of the analyte, etc. the regression line must pass through the origin (within the random error of the experimental values). This is a prerequisite for the establishment of a single-point calibration and of the 100% method for the determination of impurities. The so-called single-point calibration represents, in fact, a two-point calibration line where one point equals zero and the other the standard concentration. The zero intercept can be demonstrated statistically when the CI (usually at 95% level of significance) of the intercept includes zero. Again, such a statistical test should be interpreted carefully and a statistical significance should be evaluated with respect to its practical relevance. On the other hand, a large variability can obscure a substantial deviation of the intercept from zero. Therefore, as an absolute parameter, the intercept should be expressed as a percentage of the analytical signal of a 100% working concentration. For the acceptance limit, a basis for orientation may be sought in an acceptable value for the precision (e.g., 1%–2% for

assay). In fact, this approach can be regarded as an extrapolation of the variability at the working concentration to the origin. In order to avoid weighting effects, very large extrapolation may be disadvantageous. Even if the required range for an assay determination is 80%–120%, the linearity for a single-point calibration should be validated starting with approximately 10%–50%.

Accuracy

Accuracy by Comparison. For drug substance, the only possibility of a quantitative assessment of accuracy is the comparison to the results of another analytical procedure or to a reference (if established with other procedures and/or additional characterization). This can be performed statistically with a *t*-test (see statistical textbooks or corresponding software). However, the shortcomings of these statistical tests (or better the justification of their use) are especially important here. It must be taken into consideration that two independent analytical procedures most probably differ in their specificity. This may lead to a systematic influence on the results (Table 2). If the effect can be quantified, the means should be corrected before performing the statistical comparison. If a correction is not possible, the presumptions of the statistical test are violated and the *t*-test should

Table 2 Investigation of accuracy by comparison of an LC assay procedure with a nitrogen determination according to Dumas. The content obtained from the latter is corrected for the amount of impurities determined with LC. The critical value for the mean *t*-test is larger than the tabulated one, therefore, a (statistically) significant difference of the means is observed. However, the absolute difference between the two procedures, which have a completely different methodology, is only 0.89%

No.	Content LC (%)	Content N (%)
1	92.93	94.18
2	91.32	93.22
3	92.66	92.84
4	93.50	92.77
5	92.41	92.58

Critical value	2.11	
Test value	2.38	

consequently not be performed. Instead, it should be evaluated if the absolute magnitude of the difference is below an acceptable value (e.g., 2%).

Accuracy by Recovery. Interferences between the matrix (placebo) and the analyte, adsorption within the equipment, incomplete extraction of the analyte during the sample treatment, degradation, etc. can be verified by spiking known amounts of the analyte to the matrix (placebo). For example, drug substance is spiked to placebo (reconstituted drug product) or impurities/degradants are added to drug substance or drug product and are subsequently analyzed. This should be performed as near as possible to the authentic conditions. Ideally, the drug product is prepared with different contents of active ingredient. The least authentic approach would be the addition of standard stock solutions to a placebo solution.

The recovery can be calculated either at each level separately as a percent recovery, or as a linear regression of the found analyte vs. the added one (recovery function) (Table 3).

In the former case, it can be tested, whether the recovery mean differs significantly from the theoretical value of 100% (e.g., by the inclusion of 100 within the 95% CI). However, again it should also be taken into consideration if the absolute magnitude of the difference is acceptable, especially with respect to impurities in low concentration ranges.

With respect to the recovery function, the slope and intercept can be tested vs. the theoretical values of 1 and 0 (by their 95% CIs) or vs. acceptable limits for deviation. Due to the different weighting effects, the two approaches might lead to different results. The percent recovery calculation gives easily interpretable results and should therefore be preferred, at least for narrow working ranges.

It is absolutely essential that the accuracy be validated with the same quantitation method that is used in the control test procedure. Recovery deviations from the theoretical values while performing a calibration with a drug substance alone may indicate interferences between the analyte and placebo components. In such a case, the calibration should be done with a synthetic mixture of placebo and drug substance standard. Such interferences may also be detected by the separate determination of linearity for dilutions of the drug substance and for a spiked placebo.

Precision

Precision should be measured using homogenous, authentic samples. According to the ICH recommendation of nine determinations over the whole range, it may also be

Table 3 Investigation of accuracy by recovery. Drug substance was added in the solid state to a granulation of placebo tablets in a range from 80% to 120% of the nominal content of 50 mg. The further sample preparation is performed according to the control test

measured using artificially prepared samples or sample solutions, combining the validation characteristics linearity, accuracy, and precision in one experimental series. However, it should be noted that a larger variability can result due to the additional preparation steps. On the other hand, problems of the sample homogeneity and of the sampling itself cannot be detected.

It is essential to be absolutely aware of the different levels of precision, especially if acceptance limits are defined or if the resulting variabilities are used for further calculations. Often, the real uncertainty of results is underestimated, especially with respect to long-term applications.^[32] The large variability of the experimentally determined standard deviation has also to be taken into account (Fig. 8).

In addition to the ICH levels repeatability and intermediate precision, the system precision, i.e., repeated injections/determinations of a single sample solution (also referred to as injection repeatability or injection precision), provides valuable information. Evaluation of these data will help us to show that the chosen equipment is suitable for its intended use. Injection precision will also

become part of the system suitability requirements of the method and an acceptance criterion should be appropriately set. In the EP, a procedure is described which links the maximum permitted injection precision with the specification limits, thus allowing a specific evaluation of the suitability.^[23] However, this approach requires that the specification limits are established appropriately, i.e., taking the analytical and manufacturing variability into account.^[33]

The various levels of precision may be calculated by means of an analysis of variances.^[34] The overall variation is divided into the contributions within and between the series, allowing us to assess the most sensitive part of the analytical procedure as well as the robustness (see Table 4). Acceptance limits for assay determinations can be derived from specification limits established on the basis of experience and the analytical state of the art. With the former approach, the suitability of either the specification limits or the precision of the analytical procedure is tested. Typical RSDs for system precision of LC assay procedures should range below 1%, for repeatabilities up to 1–2%, and for intermediate precision/reproducibility twice the

Fig. 8 Repeatability standard deviations for several types of drug substance assay procedures obtained from collaborative studies. The standard deviations from six determinations are ranked in order of increasing values. Cochran's test was applied to remove outlying SDs (not shown). The reproducibility was calculated from the remaining means after passing Grubb's outlier test. For procedures a–c, the true content is 100%, for d the overall mean is calculated to 96.77%. (Blue line) Potentiometric titration of racemic ephedrine hydrochloride. Thirty-nine laboratories participated, two were removed. The mean repeatability and the reproducibility are 0.41 and 0.64, respectively. (Red line) UV spectrometry of prednisolone acetate (specific absorbance). Sixty-four laboratories participated, 12 were removed. The mean repeatability and the reproducibility are 0.63 and 1.38, respectively. (Green line) UV spectrometry of cinnarizine (specific absorbance). Sixty-four laboratories participated, seven were removed. The mean repeatability and the reproducibility are 0.82 and 1.91, respectively. (Black line) LC of cloxacillin sodium. Thirty-four laboratories participated, one was removed. The mean repeatability and the reproducibility are 0.65 and 0.60, respectively. (Data from Ref. 36.)

value for the (average) repeatability can be expected (depending on the amount of variations, time period, etc.).^[35,36] For impurity determinations, the variability is strongly dependent on the concentration level. The reproducibility of the sum of impurities can sum up between 10% and 30%.^[37]

Detection and quantitation limit

One should be aware that the determined QL (or DL) is strongly related to the equipment used at the time of determination. They may represent more system parameters than characteristics of the analytical procedure.^[16,37] They are also dependent on the calculation procedure applied.

In cases where a general QL is required, as in pharmaceutical analysis, it is essential to define a realistic QL (or DL) for the analytical procedure, independently from the equipment used, because this limit has important consequences (e.g., for the consistent reporting of

impurities or for method transfer). They may be derived by taking QL (or DL) from various instruments into account ("intermediate QL," during the development process) or can be defined taking the requirements of the control test (specification limits imposed by toxicology or by a qualified impurity profile) into consideration. For example, a QL which amounts to 50% of the specification limit would allow an appropriate quantitation. For unknown impurities, the ICH reporting thresholds of 0.05% or 0.03%^[4,5] can be defined as QL. During validation, it is just verified, that the actual QL is below the defined limit (regardless of how much below).^[38] For this purpose, each of the approaches described in the ICH guideline can be used.

Calculation from noise. For chromatographic methods, DL and QL can be calculated from the noise. Here the (random) fluctuations of the baseline performing a blank injection is regarded as "noise." It is recommended to obtain the difference between the highest and the lowest signal (amplitude) in a range corresponding to at least 20 peak widths of the (expected) analyte peak.^[39] This is a very straightforward procedure, but is dependent on the

operator.^[40] Care should also be taken to avoid the interpretation of baseline trends as “noise.” Only noise signals with a “peak width” similar to the analyte to be determined can influence its detection and determination. It should also be taken into account that the results represent signal (peak) heights.

Calculation from Linearity. For approaches based on a regression line, it must be taken into account that the residual standard deviation is strongly influenced by the absolute magnitude of the signal values (weighting effect, homogeneity of variances) and therefore by the concentration range used for the linear regression. This range should not exceed the 10-fold of the DL. In this range, the variances can be expected to be homogeneous.

Another approach is directly based on the dispersion of the experimental data in the low concentration range,^[41] represented by the prediction interval of the regression line. This interval can be interpreted as the probability distribution of (future) determinations, which can be experimentally expected. The upper 95% limit of the analyte concentration, whose probability distribution has a 50% overlapping with the distribution of the blank (Fig. 9, B) (and therefore a 50% error rate), is defined as

the DL (Fig. 9, DL). With respect to the QL the overlapping is reduced to 5% (Fig. 9, QL). Hence, a reliable quantification is possible in the latter case.

Estimation from Precision. The QL can also be obtained from precision studies. For this approach, decreasing analyte concentrations are analyzed repeatedly. The RSD is plotted against the corresponding concentration. If a predefined limit is exceeded (e.g., 10% or 20%), the corresponding concentration is established as the QL.^[15] However, a sufficiently large number of analyte concentrations must be analyzed due to the large scattering of the standard deviations in the low concentration range (Fig. 10). This approach can be simplified if a defined QL is to be verified. Then, a sample containing the impurity at the defined QL is repeatedly analyzed. If the obtained RSD is below the predefined limit, the analytical procedure has a suitable sensitivity.

If varying concentrations are used to obtain DL and QL, available impurities and degradants should be spiked to the drug substance or drug product. Different contents can also be obtained by mixing impurity-free and impurity-containing batches. The concentration of the active or matrix components (placebo, cleaning solutions) should be maintained

Fig. 9 Calculation of the detection and quantitation limits from the 95% prediction interval of the regression line. LC peak areas were obtained for six analyte concentrations between 0.05 $\mu\text{g/ml}$ and 1 $\mu\text{g/ml}$ with six repeated injections each. The regression line is shown with the 95% prediction intervals (dotted lines) in the lower concentration range. The probability distributions of the blank (B, black curve), of the analyte concentration corresponding to the detection limit (DL, blue curve) and the quantitation limit (QL, red curve) are indicated. The limits of the 95% prediction interval represent the 95% limits of the probability distribution of the corresponding concentration, i.e., the interval around the concentration where (future) experimental results can be expected in 19 out of 20 cases. All experimental results within the probability distribution of the blank (gray shaded area) cannot be distinguished from the blank. This amounts to 50% of all values in the case of the detection limit and 5% for the quantitation limit.

at the nominal level of the test. The QL of unknown substances can be obtained using representative peaks or inferred from the QL of known impurities/degradants.

The validity of the determined DL/QL should be routinely confirmed within the system suitability test (visually or from the signal-to-noise ratio).^[37]

Robustness

Deliberate variations in the parameters of a procedure will provide an estimate of its reliability in routine use. The extent of robustness studies will depend upon the type of method but this evaluation should be considered during the development phase.

Typical variations might include extraction time, flow rate through a testing device, stability of test solutions, etc. For chromatographic methods, typical variations for robustness studies would include different columns, temperature, flow rate, mobile phase pH, and organic content. Experimental design may be used during robustness experiments to develop a matrix approach to these studies,^[42,43] as well as HPLC optimization software. However, care should be taken to incorporate relevant variables into a quantitative statistical design. Otherwise, unnecessary workload is created, for example, if the investigated effects will influence the quantitation of

sample and standard identically such as flow rate, organic modifier, column, etc. These effects should only be investigated with respect to resolution.

A quantitative measure of the robustness of an analytical procedure is the different levels of the intermediate precision and their comparison (analysis of variances) (Table 4). Of course, this approach only addresses random effects, which depend on the extent of variations designed in the inter-

Fig. 10 Relative standard deviations obtained from six repeated injections of analyte concentrations from 0.05 $\mu\text{g/ml}$ to 1 $\mu\text{g/ml}$. Two series on the same LC system are shown, approximately 8 weeks apart. For illustration purposes, an arbitrary acceptance limit of 5% RSD for the injection precision is displayed.

mediate precision studies. In case of insufficient robustness, it will be often not possible to identify its source. In these cases, a systematic investigation is required.

If the robustness studies indicate that the experimental data are susceptible to variations in the method parameters, the appropriate system suitability requirements should be established to ensure the validity of the analytical procedure during routine use.

System suitability tests

The validation of an analytical procedure produces performance parameters of a “well-behaved” and “well-conditioned” system/instrument (including defined variations) which are more or less “snapshots” of the combination procedure/system. In order to routinely confirm the suitability of the integrated measurement instrumentation used with a given procedure, system suitability test parameters should be defined on the basis of the validation results and robustness studies. Larger variations under routine conditions or multiple laboratories should also be taken into consideration.

The extent of the system suitability testing is dependent on, for example, the stage of drug development, the objective of the analytical procedure, the availability of reference substances, etc. The following parameters may be considered:^[23,37,44,45]

- Comparison with a test chromatogram of reference standard (cf. retention times).
- System precision (injection repeatability); acceptance limit for LC: 2% RSD,^[44] for drug substance dependent on the (upper) specification limit [e.g., 102.0% and $n = 6$: 0.85%].^[23]
- Resolution factor—acceptance criteria: not less than 2.0 (recommended with respect to the main peak).
- Number of theoretical plates.
- Tailing factor—acceptance criteria: between 0.5 and 2.0 (recommended).
- Pressure drop.
- Baseline drift.
- (Detector) linearity or sensitivity at different concentrations.
- DL/QL (e.g., as signal-to-noise ratio—acceptance criteria: not less than 3 and 10, respectively).

Validation During Drug Development and Manufacturing

The ICH requirements are intended for the submission of new pharmaceuticals. Good manufacturing practice regulations, which include analytical procedures for

in-process controls, QC of excipients, starting materials, intermediates or during drug development prescribe no details of validation requirements. In these applications, the ICH guidelines should be used for orientation with an increasing expenditure of effort and requirements as development or manufacturing progresses. For validation purposes, three distinct levels can be described for which validation requirements can be defined.

Level I

Level I is intended for analytical procedures during the early development (preclinical phase), for starting materials and in-process controls. At this stage of development, relatively small quantities of drug substance are available, analytical reference standards have not been established, and little information is available regarding synthesis or degradation impurities. Also, frequent changes/improvements in drug substance and formulations are expected. As such, the validation that is conducted is at a minimum. Validation data may be extracted from routine testing. The specificity can be demonstrated using available batches and samples from stress testing in combination with simple variations in the chromatographic conditions (gradient, elution time, pH). For demonstration of linearity, a dilution of the analyte is performed (detector linearity). Accuracy is inferred from specificity, linearity, and precision. A system precision is performed with six injections. QL is defined visually. The results are summarized and evaluated in order to make a statement on the suitability.

Level II

Level II is applied for drug substances and products during the early clinical phases and for intermediates. At this stage of development, drug substance synthetic processes are becoming finalized and higher quality material is available in larger quantities. A drug substance reference standard is established and information is increasingly available on synthetic and degradation impurities. Reference standards are established for impurities as they become available. Formulation development activities are giving rise to finished products to be used in clinical studies. It is at this stage that formal control tests must be established. The validation effort is significantly extended from Level I. Specificity is investigated using various batches, available impurities, excipients, and samples from stability testing. Investigations on peak purity may be performed. The linearity of the detector or of the procedure, depending on the complexity of the latter, is validated. Accuracy is inferred (drug substance)

or obtained from three determinations of the recovery at the working concentration. A repeatability study ($n = 6$), or depending on the application of the procedure, an intermediate precision is performed. Quantitation limit is obtained visually or verified with one of the quantitative approaches. The documentation consists of a short summary of the performed investigations and an evaluation of the results.

Level III

Level III is applied during clinical phase III and for the submission, as well as for important intermediates, and corresponds to the ICH requirements. At this stage of development, the commercial synthetic process for drug substance is established, and important process and degradation impurities have been identified and synthesized. The final formulations and dosages have also been established.

A full validation report is required with description and justification of the design of the experimental studies, and a detailed discussion and evaluation of the results.

In all levels, validation software can be used to standardize and to improve the efficiency of documentation of the data and calculations. However, it should be flexible enough to allow the necessary case-by-case (or type-by-type) design of the validation.^[19]

Maintenance of the Validation Status

In several guidelines, the term revalidation is mentioned,^[2,10,12] sometimes in more detail.^[15] However, one should be aware that validation is always more or less a “snapshot” of the actual state of the overall system equipment—analytical procedure. Therefore, it should be regarded as a basis, i.e., the proof of the general suitability. If adjustments of the analytical procedure are restricted to the validated and recommended ranges,^[23,45] there is no rationale, for a repeated validation. Only if a procedure is changed, a new validation is required.

Of course, it must be guaranteed that the analytical procedure is consistently in a validated state. This can be achieved by monitoring appropriate SST results. Another possibility is to perform (regularly) supplementary investigations such as further intermediate precision studies, which can be included in the routine analysis. With this approach, it is possible to supplement and extend existing information and to take the very important time factor into proper consideration. Information can be obtained on the long-term behavior of an analytical procedure and therefore on the reliability in routine use,

Fig. 11 Relative standard deviations of reference standard preparations for an LC assay procedure over a period of about 10 months. The RSDs were calculated from four injections of two independent preparations each. Fifty-eight results were obtained, two of them exceeded the defined limit of 2.0% (3.85% and 3.94%, not shown). The average RSD (0.88%) is indicated by a blue line. (Data courtesy of Dr. C. Korn, Aventis, Germany.)

for example, better estimates on the true (long term) analytical variability.

In Fig. 11, SST precision results for more than 10 months during drug development are shown. The RSDs were calculated from the standard preparations of an assay procedure, i.e., from four injections of two separate preparations (single-point calibration). Therefore, the variability represents a combination of system precision and repeatability. It should be noted that with an average of 0.88% (representative for the true value with 58 runs over 10 months), the single results scatter regularly up to 1.6%. Two-thirds of all RSDs range between 0.5% and 1.3%. In two cases (about 3%) the RSDs exceed the SST limit of 2.0%. This was attributed to gross (weighing) errors.

Quality control charts are a very effective approach to investigate not only the analytical variability, but also the accuracy. Due to the accumulation of results, additional forms of statistical analysis (statistical process control, SPC) become possible. The continuous monitoring and the proof that the analytical procedure is in statistical control allows a reliable evaluation of the underlying process (e.g., batch manufacturing) and an early detection of trends. Fig. 12 represents a control chart for an LC content determination of an injection solution. A control batch (“dummy”) was analyzed with a single determination each time the analytical procedure was applied (over about 6 months). The target mean and the standard deviation were calculated from the first 20 determinations and normalized to 100%. All but one result are within the control limits (\pm three standard deviations around the

Fig. 12 Control chart of a single LC determination of an injection solution. The mean and the SD were calculated from the first 20 determinations. The mean is normalized to 100% (blue line). The control limits (red lines) correspond to threefold of the RSD. The experimental results are displayed consecutively and connected by a black line to facilitate the recognition of systematic pattern. The blue arrow indicates the use of a new standard solution after an out-of-control event (red arrow). Data by courtesy of Dr H.-J. Ploss, Aventis Germany.)

mean). The group of values preceding the outlying one (red arrow in Fig. 12) was obtained with the same standard solution and is shifted toward the upper control limit. For the next run (blue arrow in Fig. 12), a new standard solution was prepared. The “normal” result of 99.0% indicates that the shift was caused by a deviating standard preparation. The deviation from the mean is with less than 1.5% in the range of the expected analytical variability (for a single determination) and therefore difficult to detect in routine batch analyses. In contrast, such shifts and also trends can easily be detected in a control chart representation. Besides limit violations, the control chart can also inspected for “abnormal” (systematic) patterns, such as six points steadily increasing or decreasing, 14 points in a row alternating up and down, etc. (for details, see [46]). This provides the chance not only to obtain reliable (long term) information on the analytical system, but also to adjust it proactively.

Such a continuous process of analytical validation can be regarded in analogy to the qualification process.^[47d,48] With respect to the four Qs (design, installation, operational, and performance qualification), three Vs can be defined: design, operational, and performance validation. “Design validation” involves the method

development, where the basic performance requirements are established. During the “operational validation,” it is verified that these requirements are generally met, i.e., this part corresponds to the “conventional” validation. Performance validation consists of a continuous monitoring of the validation status of an analytical procedure.

CONCLUSIONS

Instead of an isolated and formal “checklist” activity, validation of analytical procedures should be regarded as part of an integrated quality assurance concept to guarantee the accuracy and reliability of the analytical results and therefore quality, safety, and efficacy of pharmaceuticals.

For such an integrated system, all parts (such as equipment qualification, performance of the analytical procedure, analytical variability, specification limits, etc.) must be compatible with each other to prevent (analytically caused) out-of-control or OOS results. On the basis of the validation characteristics and requirements of the ICH guidelines, each analytical procedure must be validated with respect to parameters, which are relevant to its performance. It is the responsibility of the analyst to identify these parameters and design the

^dhttp://dg3.eudra.org/pharmacos/gmp_doc.htm.

validation study accordingly. Acceptance criteria should be defined in the validation protocol. They can be established from previous experiences (analytical state of the art) or calculated from specification limits. For the intended use of the test procedure acceptable absolute acceptance limits are preferred. Statistical tests should be used carefully and preferably for orientation purposes. The evaluation of the validation results is the responsibility of the analyst and must not be left or reduced to the outcome of a statistical test! However, statistical analysis and consideration are very helpful in verifying the compatibility of specification limits and analytical variability, calculating acceptance limits, and performing simulations in order to predict future risks.

By monitoring the validation status of the applied analytical procedure, for example, with control charts, reliable information on the long-term behavior of the procedure can be obtained and trends can be detected very early. Transferring in this way data to information to knowledge, the analytical system (or the production process) can be adjusted before problems such as OOS results occur (action instead of reaction). In analogy to equipment qualification, a continuous system is proposed: design, operational, and performance validation (three Vs).

VALIDATION OF PHARMACEUTICAL PROCESSES

Robert A. Nash

Consultant, Mahwah, New Jersey, U.S.A.

INTRODUCTION

Process validation is a requirement of current Good Manufacturing Practices (GMPs) for finished pharmaceuticals (21 CFR 211) and of the GMP regulations for medical devices (21 CFR 820) and therefore applies to the manufacture of both drug products and medical devices.

According to the FDA Guidelines on General Principles of Process Validation (1), process validation is defined, "... as establishing documented evidence, which provides a high degree of assurance, that a specific process will consistently produce a product meeting its predetermined specifications and quality characteristics." The process for making a drug product consists of a series (flow diagram in logically defined steps) of unit operations (modules) that result in the manufacture of the finished pharmaceutical.

There is much confusion regarding the definition of process validation and what constitutes process validation documentation. The term validation is used here generically to cover the entire spectrum of current GMP concerns, essential most of which are; facility, equipment, component, method, and process qualification. Based upon the FDA process validation guidelines (1), the specific term should be reserved for the final stage(s) of the product and process development sequence. The essential or key steps or stages of a successfully completed development program are shown in Table 1.

The end of the development sequence, which should be assigned to formal (three-batch) process validation, derives from the fact that the specific exercise of process validation should never be designed to fail. Failure in carrying out the formal process validation assignment is often the result of incomplete or faulty understanding of the process capability, in other words, what the process can and cannot accomplish under a given set of operational requirements.

In a well-designed validation program, most of the effort should be spent on facilities, equipment, components, methods, and process qualification. In such a program, the formalized, final three-batch validation sequence provides only the necessary process validation documentation required by the FDA to show product reproducibility and a manufacturing process in a state of

control. Such a strategy is consistent with the FDA preapproval inspection program directive (2).

PROCESS VALIDATION OPTIONS

The guidelines on general principles of process validation (1) mention three options: prospective process validation (also called premarket validation), retrospective process validation, and revalidation. Actually there are four, if concurrent process validation is included.

Prospective validation is carried out prior to the distribution of a new product or an existing product made under a revised manufacturing process where such revisions may affect product specifications or quality characteristics. The prospective approach features critical step analysis in which the unit operations are challenged during the process qualification stage to determine those critical process variables that may affect overall process performance, using either worst-case analysis or a fractional-factorial design. During formal, three-batch, prospective validation, critical process variables should be set within their operating ranges and should not exceed their upper and lower control limits during process operation. Output responses should be well within finished-product specifications.

Retrospective validation is recognized in both current GMPs [21 CFR 211.110(b)] and the FDA process validation guidelines (1). It involves accumulated in-process production and final product testing and control (numerical) data to establish that the product and its manufacturing process are in a state of control. Valid in-process results should be consistent with the final specifications of the drug product and shall be derived from previous acceptable process average and process variability estimates where possible and determined by the application of suitable statistical procedures (quality control charting) where appropriate.

The retrospective validation option is chosen for established products whose manufacturing processes are considered to be stable and when, on the basis of economic considerations and resource limitations, prospective qualification and validation experimentation cannot be justified.

Table 1 Development sequence with respect to process validation

Developmental stages	Batch size
Product design	1 X
Product characterization	
Product selection	
Process design	
Product optimization	10 X
Process characterization	
Process optimization	
Process qualification	
Process qualification	100 X
Process validation	
Process certification	
Process revalidation	100 X to 1000 X

Prior to undertaking either prospective or retrospective validation, the facilities, equipment, and subsystems used in connection with the manufacturing process must be qualified in conformance with cGMP requirements.

Concurrent validation studies are carried out under a protocol during the course of normal production. The first three production-scale batches must be monitored as comprehensively as possible. The evaluation of the results is used in establishing the acceptance criteria and specifications of subsequent in-process control and final product testing. Some form of concurrent validation, using statistical process control techniques (quality control charting) may be employed throughout the product manufacturing life cycle.

Revalidation is required to ensure that changes in the process and/or in the process environment, whether introduced intentionally or unintentionally, do not adversely affect product specifications and quality characteristics (2). There should be a quality assurance program (change control) in place which requires revalidation whenever there are significant changes in formulation, equipment, process, and packaging that may impact on product and manufacturing process performance (3). Furthermore, when a change is made in a raw material supplier, the drug manufacturer should be made aware of subtle, potentially adverse differences in raw material characteristics that may adversely affect product and manufacturing process performance.

It is recommended that every requested change be reviewed by the validation or CMC committee. Such a committee should judge if a change is significant for revalidation and decide on a course of action to be taken. The following conditions require revalidation study and documentation:

1. Change in a critical component (usually refers to active pharmaceutical ingredient, key excipients, or primary packaging);
2. Change or replacement in a critical piece of modular (capital) equipment;
3. Significant change in processing conditions that may affect subsequent unit operations and product quality;
4. Change in a facility and/or plant (usually location, site, or support systems);
5. Significant increase or decrease in batch size that affects the operation of modular equipment; and
6. Sequential batches that fail to meet product and process in-process specifications.

In some situations process performance requalification studies may be required prior to undertaking specific revalidation assignments. With the exception of sterile products manufacture, periodic revalidation is not required at the present time. The performance and state of control of the product and its manufacturing process can be adequately covered during the annual product and process review. The FDA has issued an interim guidance document that addresses what constitutes major and minor formulation and manufacturing changes for immediate-release solid dosage forms (4). Such documentation and others to follow should simplify manufacturing decisions about the need to revalidate.

VALIDATION PRIORITIES

There is a basic concept with respect to which pharmaceutical processes should be given a higher priority over others. All pharmaceutical manufacturing processes require process validation documentation, but there is an accepted logical approach to priority selection, in the following order:

Sterile products and their processes

- large volume parenterals (LVPs) infusions greater than 100 ml
- small volume parenterals (SVPs) single and multiple dose injections
- ophthalmics and sterile devices

Nonsterile products and their processes

- low dose high potency tablets and capsules
- drugs with inherent stability problems
- transdermal delivery (TDD) and inhalation products
- the rest of the oral solid dosage forms
- oral liquids and topical products

The best approach to assessing problems with respect to a terminal sterilization method (i.e., moist heat, dry heat, radiation, and chemical methods) is to first establish the qualification, validation and stability of the pharmaceutical process prior to conducting a given sterilization procedure.

THE VALIDATION COMMITTEE

In most companies, the validation or Chemistry, Manufacturing and Control (CMC) committee is charged with the responsibility of establishing and operating the complete validation program for the specific manufacturing site. In some companies the program is led by a validation manager whereas in others, quality assurance personnel have taken on expanded responsibilities in this regard.

Specific process validation assignments are carried out by those with the necessary training and experience. The specifics of how the committee is organized to conduct process validation assignments is beyond the scope of this article. The responsibilities that must be carried out and the traditional organizational structures best equipped to handle each of these assignments are outlined in Table 2. Other members may include Quality Control, Regularity affairs, etc.

VALIDATION MASTER PLAN

The creation of a master plan permits the development of a logical overview of the validation effort. It lays out in a logical sequence the activities or key elements or both to be performed in accordance with the approximate time schedule in a Gantt or PERT chart format. The master plan establishes the critical path through the chart against which progress can be monitored.

The validation program starts with the design and development of raw materials and components, followed by the IQ/OQ of facilities, equipment, and systems through performance and process qualification stages, and terminates in the protocol-driven, three-batch, formal process validation

program. Most of these activities move forward in series. However, by combining activities and elements and moving in parallel, where possible, on independent tracks with respect to active pharmaceutical ingredients (APIs) analytical methods development, facilities, equipment, support systems, and the drug product design and manufacturing process development, a great deal of time can be saved before the individual elements or grouping of activities are combined prior to the formal process validation program. A Process Validation progress chart is shown in Fig. 1.

Installation Qualification (IQ)

This includes procedures and documentation to show that all important aspects of the installation of the facility, support system, or piece of modular equipment, having been properly calibrated, meet its design specifications and that the vendor’s recommendations had been suitably considered.

Operational Qualification (OQ)

Following IQ, procedures and documentation show that the facility, support system, or piece of modular equipment perform as intended throughout all anticipated operating ranges under a suitable load.

Performance Qualification (PQ)

Following IQ and OQ, actual demonstrations during the course of the validation program show that the facility, support system, or piece of modular equipment perform according to a predefined protocol and achieve process reproducibility and product acceptability.

VALIDATION PROTOCOL AND REPORT

The following validation protocol and format for the completed validation report have been suggested in the WHO Guidelines on Validation of Manufacturing Processes (TRS 823) (5).

Table 2 Composition of the process validation committee

Representative of	Function
Engineering	Qualifies for plant, facilities, equipment, and support systems
Development	Qualifies for products and their specific manufacturing processes
Manufacturing	Operates plant, facilities, equipment, support systems and the various manufacturing processes
Quality assurance	Audits plant, facilities, equipment, support systems, the various manufacturing processes, and their products

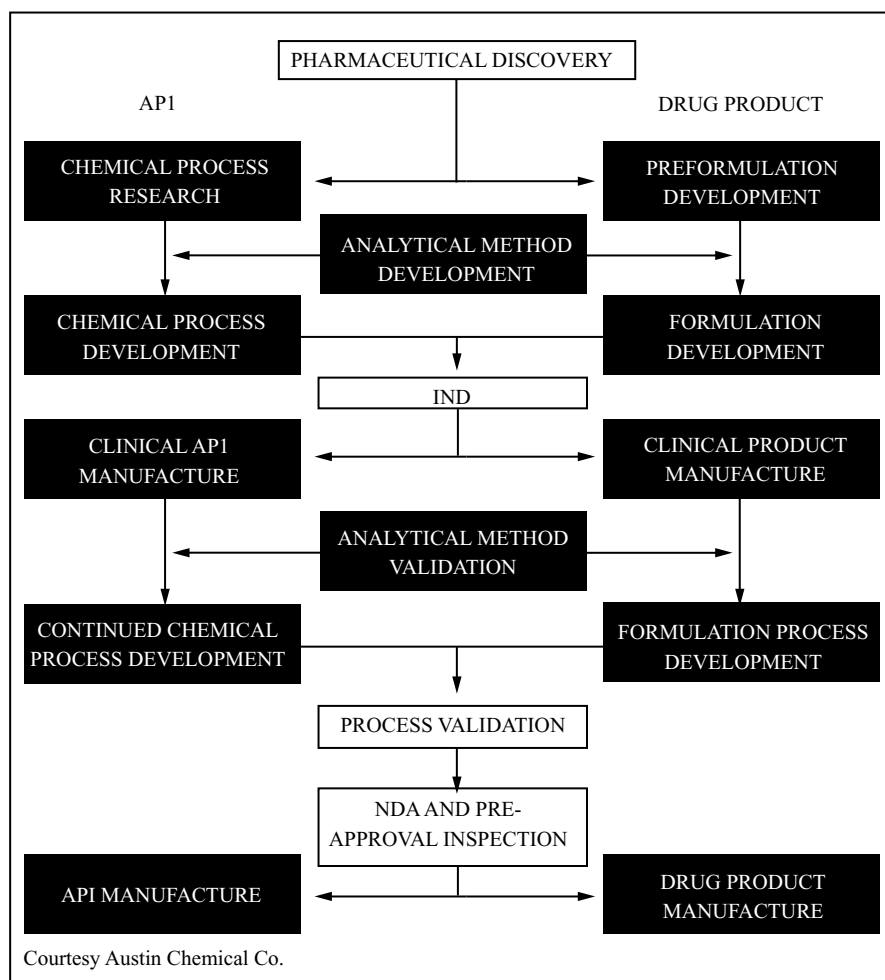

Fig. 1 Process validation progress chart.

1. Purpose (for the whole validation) and prerequisites
2. Presentation of the whole process and subprocesses including flow diagram and critical step analysis
3. Validation protocol approvals
4. Installation and operational qualifications, including blueprints or drawings
5. Qualification report(s)

- Subprocess 1
- Purpose
- Methods and procedures
- Sampling and testing procedures, release criteria
- Reporting function
- Calibration of test equipment
- Test data
- Summary of results
- Approval and requalification procedure
- Subprocess 2 (repeat)

6. Product qualification, test data from prevalidation batches
7. Product validation, test data from three formal validation batches
8. Evaluation and recommendations (include revalidation and requalification requirements)
9. Certification (approval)
10. Summary report with conclusions

The validation protocol and report may also include copies of the product stability report or its summary as well as validation documentation on cleaning and analytical methods.

PREAPPROVAL INSPECTION

The FDA Preapproval Inspection Program (2) is designed to provide a basis for determining the adequacy and

accuracy of reported and factual information in New Drug Application (NDA) and Abbreviated New Drug Application (ANDA) submissions with respect to the suitability of cGMP product development, analytical laboratory, and manufacturing facilities.

A preapproval inspection checklist should include the following documentation which may be required prior to the formal inspection:

1. API development and validation report(s) including impurity profile and polymorphic forms;
2. Pharmaceutical (dosage form) development report;
3. Stability and clinical batch records and history, including phase-III program;
4. Data for API and key excipients used in the manufacture of clinical and biobatches;
5. Bioequivalency report;
6. Technical transfer report (development to manufacturing/QA/QC);
7. Copy of the CMC section of the NDA including information on suppliers and vendors;
8. Copy of proposed production monograph and master batch record;
9. Equipment validation report establishing IQ and OQ;
10. Cleaning validation report;
11. Analytical methods validation and computer systems validation reports;
12. Stability report establishing expiry dating; and
13. Process validation protocol for formal three-batch validation of production-size batches.

During preapproval inspection, the FDA accepts a process-validation protocol based on the company's commitment to complete successfully three production-size validation batches prior to product launch. In some situations a prevalidation (process demonstration qualification) production-size batch is completed before the entire formal three-batch program is carried out.

PILOT SCALE-UP AND TECHNOLOGY TRANSFER

The pilot-production program may be carried out as a shared responsibility between the development laboratories

and their appropriate manufacturing counterpart or as a process demonstration by a separate, designated pilot-plant or process development department. Supporting technology transfer documentation applies to both the specific process and system being qualified and validated and the related testing standards and testing methods. The formal technology transfer is normally made from the development laboratories or the process development pilot-plant to pharmaceutical production function.

In actuality, a number of technology transfer points and documents are generated as prospective validation proceeds through the various stages of product development. These stages of technology transfer in terms of scale-up are illustrated in Fig. 2.

Solid pharmaceutical dosage forms (tablets and capsules) are used to illustrate the various stages of product and process development. These principles and practices also apply in a general way to the development of liquid and semisolid pharmaceutical dosage forms (not discussed here).

STAGES OF VALIDATION

Elements of the validation concept should be incorporated during each of the various stages of the product and process development continuum. These stages can be summarized as follows.

Stage Preformulation Studies: APIs plus key excipients

- Stage I Product design and development
- Stage II Preparation of clinical and biobatches
- Stage III Process scale-up and evaluation
- Stage IV Formal process validation

Preformulation Studies: API

Preformulation testing of the specific API of interest and key excipients to be used in the product design stage, alone and in combinations with the API, should be included as a preliminary first step in the product and process development sequence. A simple check list of items

Fig. 2 Technology transfer stages.

worth consideration in preformulation studies with APIs and important or critical excipients is provided as follows:

API

- Key excipients
 - Fillers and diluents
 - Binders
 - Disintegrants
 - Glidants and lubricants
- Establish chemical and physical compatibility
- Minimize lot-to-lot variability in properties
- Worldwide availability from comparable suppliers
- Properties for possible evaluation
 - Color, odor, taste, solubility;
 - Particle morphology (DSC, TGA, x-ray diffraction);
 - Particle size distribution and surface area;
 - Crystal and bulk density, compaction index;
 - Angle of repose and flowability index;
 - Spectrophotometry (UV, FTIR, NMR, OR);
 - Water content, LOD, moisture uptake;
 - Microbial limits and heavy metals;
 - HPLC assay and impurity profile.

Before preformulation studies are undertaken, two-way technical communication between the manufacturers of the API (laboratory and plant) and the pharmaceutical product development laboratories must be established (see Fig. 1). It should start early and be maintained through-out the product and process development program.

In addition to potency, purity, and stability considerations of the API, the product development department is especially interested in the chemical and physical form (free acid or base, salts, esters, amides, polymorphs, solvates, particle size and shape) of the API. Time spent early in the cycle in establishing these particular factors often aids and/or simplifies the subsequent product and process development program.

Not every subject shown above must be tested or addressed. However, aspect, particle morphology and size, compaction and flowability, water content, spectrophotometric and chromatographic data should be studied and monitored throughout the product and process development program (6, 7).

Because key excipients are well established in most new product and process development programs, the same degree of preformulation scrutiny is often not required. Compatibility studies with the API, however, should be performed to study possible untoward interactions between the active ingredients and the excipients. It should be kept in mind that small or minor changes in

physical and possibly chemical properties upon intimate contact in binary studies with key excipients should not automatically exclude a favored excipient without further critical testing.

Stage I: Product Design and Development

Following successful preformulation studies, the API is transferred to the formulations laboratory for preliminary product design and development studies. In most cases, the drug is mixed with an appropriate diluent or filler and glidant combination and filled into two-piece opaque hard-shell capsules for preliminary stability and subsequent phase I clinical studies versus matching placebo capsules (8). At or about the same time, initial studies of a prototype tablet formulation should be started. The key steps in the product design and development sequence are given below.

Stage I: Product Design: 1× Laboratory Scale (1–10 kg)

- Hard-shell capsule (phase I clinical trials) followed by prototype tablet dosage form
 - Direct compression versus wet granulation
 - Maximize chemical and physical stability
 - Minimize product and process costs
 - Product characterization
 - Product selection
 - Process design
- Excipients are selected among the following categories:
 - Binder, diluents, and disintegrants including alginates, calcium phosphate, cellulose, dextrates, gelatin, povidones, starch and derivatives, sorbitol, sucrose, and derivatives. Glidants and lubricants including colloidal silicon dioxide, hydrogenated vegetable oil, mineral oil, PEG, silica gel, sodium lauryl sulfate, stearates, talc.

Although the work is conducted in the research or formulations laboratory using small-scale processing equipment, it is important to gain early experience with colorant systems that have been selected for the finished tablet product; color aids in blend-uniformity evaluation.

In addition to excipient screening and selection, it is important to gauge processing parameters that are more fully explored during the scale-up phases. These processing factors include flowability, compaction and compressibility of powders and granules, content uniformity of powder and granule blends and finished tablets, moisture uptake, in vitro dissolution release profiles, and subsequent full-scale stability testing.

Products used in human clinical trials must, of course, conform to good laboratory, good clinical, and good manufacturing practice requirements (1, 9).

Stage II: Process Development: Pilot Laboratory (Clinical)

After the (1X) “go” laboratory batch has been determined to be both physically and chemical stable, based upon accelerated, elevated temperature testing (1 month at 45°C or 3 month at 40°C and 80% relative humidity) the next step (stage II) is to scale the product and its process to (10X) pilot-laboratory size batch(es). This batch represents the first replicated scale-up of the designated formula. Its size usually ranges between 10 and 100 kg, 10 and 100 L, or 10,000 to 100,000 units. Often these pilot-laboratory batches are used in clinical trials and bioequivalency studies. According to the FDA, the minimum requirement for a biobatch is 100,000 units (10).

Pilot-laboratory batches are usually prepared in small pilot equipment within a designated current GMP approved facility. The number and size of these pilot-laboratory batches may vary, depending on one or more of the following factors:

- Equipment availability
- API availability
- Cost of raw materials
- Inventory requirements for both clinical and nonclinical studies

Process development (process qualification) or process capability studies are normally started in this important stage II of the scale-up sequence. The scope of stage-II process development consists essentially of product optimization and process characterization studies.

Product Optimization:

- Establish formula rationale and boundary conditions for API and excipients

Process Characterization:

- Define unit operations, process variables, and response parameters.
 - Define critical process variables and response parameters using simple experimental designs.
 - Establish provisional control limits for critical process variables and their response parameters based on process replication.
- Maintain product stability.

Unit operations for solid dosage-form development include:

- Granulation
- Drying
- Sizing
- Blending and mixing
- Encapsulation and/or tablet compression
- Coating
- Filling and packaging

Unit operations are selected for the development of a tablet (coated or noncoated) or capsule (hard shell or soft-gel) process (11). Unit operations that are considered to be critical are determined through analysis of the process variables and their respective measured response for each unit operation (Table 3) (12–14).

In order to determine critical control parameters and their unit operations, constraint analysis techniques (15) followed by fractional factorial designs (Table 4) are used to challenge the tentative control limits (so-called worst-case analysis) established for the process at this intermediate stage. Time and effort spent to qualify the process at the 10X stage often simplifies the work that follows during stages III and IV.

Von Doehren et al. (13) and Chowhan (16) have described the various stages of solid dosage form process development as it relates to technology transfer and process validation. Their respective approaches to the topic have been integrated in this article.

Fahrner (17) raises the following issues regarding the new role for pilot plants in product development.

- Too much time is devoted to preliminary or applied research and not enough to the proper development of the process.
- Often a suitable manufacturing strategy is lacking during the early phases of the program, which results in poorly planned technology transfer and an inappropriate division of responsibility with respect to the overall program.
- Most laboratory processes are rarely scalable, since piloting is a scaled-down version of manufacturing not a scaled-up version of the laboratory batch.

Fahrner makes the case for a separate pilot facility (process development function) to bridge the communication gap between R & D and production.

Stage-III: Pilot Production

The technology transfer of the product and process from the traditional product development function to a separate process development (pilot plant) function or production

Table 3 Control parameters for solid-dosage-form development

Unit Operation	Process variables (X) ^a	Measured responses (Y) ^b
Granulation (Power type)	Load Speed (main chopper) Liquid addition rate Granulation time	Power consumption
Drying	Load Inlet temperature Air-flow rate Drying time	Moisture content Bulk density
Sizing (Screening)	Load Screen size Speed Feed rate	Particle size distr. Bulk density
Blending (Mixing)	Load Speed Mixing time	Blend uniformity
Encapsulation	Fill volume Tamper setting Speed Glidant (type, amount)	Capsule weight Moisture content Dissolution Content uniformity Potency

Coating (Film type)	Load Pan speed Spray rate Air flow	Weight gain

^a7–23 possible variables.^b11–16 possible responses.

itself is normally carried out at the (100×) pilot-production batch stage (100–1000 kg):

- Full-scale production batch
- For possible future commercial or clinical use
- Evaluate critical process parameters; product and process are scaled to another order of magnitude (100×)
- Process optimization
 - Mixing and blending times
 - Drying times
 - Milling operations
 - Press speed, compression force
 - Encapsulation speed, tamping settings
 - Speed, air flow, spray settings, temperature

- Process qualification (prevalidation batches); determine process capability, challenge in-process control limits
- Maintain product stability

The creation of a separate pilot plant or process development unit has been favored in recent years because it is ideally suited to carry out key process qualification and/or process validation studies in a timely manner (18, 19).

The objective of the pilot-production batch is to scale the product and its process by another order of magnitude (100×). For most solid dosage forms it represents a full production scale batch, in standard equipment. The technology transfer documents should include the technical information normally required for preapproval inspection:

Table 4 Fractional factorial design for process development^a

Trials	Key variables ^b							Sums
	X ₁	X ₂	X ₃	X ₄	X ₅	X ₆	X ₇

^aAdapted from Hendrix, C. D., What every technologist should know about experimental design, *CHEMTECH* (March 1979).

^bKey variables are randomly assigned an “X” value.

1. Preformulation information
2. Product development report
3. Product stability report
4. Analytical methods report
5. Proposed manufacturing formula, manufacturing instruction, in-process and final product specifications at the 100X-batch size

The objectives of prevalidation trials at stage III (100X pilot production) is to qualify and optimize the process in full-scale production equipment and their facilities.

Rushing through the first (100X) pilot-production batch in order to proceed with formal validation should be discouraged. Small problems that often arise during (100X) scale-up should be addressed immediately and not ignored. Such problems are often best addressed by returning to the laboratories (10X) for supplemental process characterization and qualification studies.

Many companies, however, proceed directly to three-batch formal validation without stage III prevalidation work and often complete formal trials prior to preapproval inspection. The downside of this alternative strategy is that finished production batches often remain in the warehouse beyond their approved expiry dating period.

When faced with a choice of strategies, there is no one ideal way of completing the pilot scale-up and validation sequence other than depending on prior experience with related products and their processes.

Stage-IV: Formal Process Validation

In the normal course of events and following a successfully completed preapproval inspection, formal, three-batch

process validation is carried out in accordance with the protocol approved during the preapproval inspection. The primary objective of the formal process validation exercise is to establish process reproducibility and consistency. The program is not designed to challenge upper and lower control limits (so-called worst-case analysis) of critical process variables. Such upper and lower control limit challenging is normally conducted during the stage II (10X size) process characterization, optimization, and qualification program, using suitable and reasonable experimental designs (Table 4).

The documentation to be established before, during, and after formal process validation is shown below. The protocols and the subsequent formal validation studies are designed to establish uniformity among the three batches with respect to granulation, blending, finished tablet, and finished capsule stages (1, 2, 10).

100X production batches

- Complete product development program and report
- Prepare protocol for prospective process validation
- Complete preapproval inspection requirements; conduct three-batch formal process validation, establish reproducibility for mixing, blending, and compression or encapsulation operations
- Establish process documentation
 - Preformulation report
 - Analytical methods validation report
 - IQ/OQ and cleaning validation reports
 - Formula development report
 - Process feasibility report
 - Manufacturing bioequivalency report
 - Product development report
 - Process validation protocol
 - Process validation report
 - Product stability report

In that respect, the following test data and results are used to show process reproducibility and consistency among validation batches: particle or granule size distribution, bulk density, moisture content, hardness, thickness, friability, weight uniformity, potency uniformity, disintegration–dissolution profile, and product stability. Not every one of these categories have to be addressed nor followed both during in-process and final product testing. Nevertheless, testing must be sufficient to establish process reproducibility and demonstrate, with a high degree of certainty, that the product and process are in a state of control.

Whenever possible, formal validation studies should continue through packaging and labeling operations (whole or in-part), so that machinability and stability of

the finished product can be established and documented in the primary container–closure system.

Recently the FDA, with the cooperation of the Pharmaceutical Industry has developed a series of guidance procedures to speed approval of post approval changes with or without process scale-up changes. At the present time the SUPAC (scale-up post approval change) program covers the following product categories:

- Immediate Release (IR) solid dosage forms
- Extended Release (ER) solid dosage forms
- Delayed Release (MR) solid dosage forms
- Semisolids (SS) dosage forms
- API changes presently called BACPAC
- Packaging changes called PACPAC
- Analytical Methods changes called AMPAC
- Sterile Aqueous Solutions called SUPAC-SAS

If the program is successful, other dosage form categories will be added later.

The following changes are covered:

- Components and Composition Changes
- Manufacturing Equipment and Process Changes
- Batch Size (scale-up) Changes
- Manufacturing Site Changes

The program consists of three levels:

- Level 1 or minor changes that are made without FDA approval and reported in the Annual Report (AR).
- Level 2 or intermediate changes that may be instituted by first filing a Change Being Effected (CBE) Supplement with the FDA and waiting 30 days for a reply before instituting the change.
- Level 3 or major change in which a prior approval supplement (PAS) is filed with the FDA and approval must be obtained from the FDA before proceeding with the change.

This new program is off to a good start and is intermittently involved with the need for adequate process validation studies and documentation to support the changes requested.

CHANGE CONTROL

Procedures with respect to establishing change control should be in place before, during, and after the completion of the formal validation program. A change control system maintains a sense of functionality as the process evolves and provides the necessary documentation trail that ensures that the process continues in a validated,

operational state, even when small noncritical adjustments and changes have been made. Such minor, noncritical changes in materials, methods, and machines should be reviewed by the validation committee (development, engineering, production, and QA/QC) to ensure that process integrity and comparability have been maintained and documented before the specific change that has been requested can be approved by the head of the quality control unit.

The change control system, based upon an approved standard operating procedure(s) (SOPs), takes on added importance as the vehicle or instrument through which innovation and process improvements can be made more easily and more flexibly without prior formal review on the part of the NDA and ANDA reviewing function of the FDA. If more of the supplemental procedures with respect to the chemistry and manufacturing control sections of NDAs and ANDAs could be covered through annual review documentation procedures, with appropriate safeguards, process validation will become more innovative (20–22).

OUT-OF-SPECIFICATIONS

Probably the single most important technical issue facing the pharmaceutical industry at the present time is the question: what constitutes process or batch failure in terms of an out-of-specification (OOS) assay value? The concept of product and/or process failure appears twice in the cGMPs (3).

According to 21 CFR Sect. 211.165(f), “Drug products failing to meet established standards or specifications and other relevant quality control criteria shall be rejected.” In CFR Sect. 211.192 it is stated:

Any unexplained discrepancy (including a percentage of theoretical yield exceeding the maximum or minimum percentages established in master production and control records) or the failure of a batch or any of its components to meet any of its specifications shall be thoroughly investigated [regardless] whether the batch has already been distributed. The investigation shall extend to other batches of the same drug product and other drug products that may have been associated with the specific failure or discrepancy. A written record of the investigation shall be made and shall include the conclusions and follow-up.

The key to establishing product and/or process failure is to verify the accuracy, relevance, and reproducibility of

deviant assay value(s), test result(s), and recorded number(s) that are reported (23). All companies should have SOPs in place that cover first the verification of deviant numbers in the quality control laboratories and, following that investigation and a report showing the test result to be deviant, a second set of SOPs covering follow-up actions taken as described in the following steps:

1. A written procedure for full investigation when there is not a verified laboratory error.
2. Scientific criteria for retesting and resampling during the formal investigation.
3. Description and results of the formal investigation into possible causes of the OOS result(s).
4. Results of all testing involved during the investigation.
5. A scientific basis and justification for discarding any OOS test result and accepting the batch in question.
6. Final determination of conformity to appropriate specifications and justification of the actions taken, and
7. Signature of individual(s) responsible for final decision(s) and the action(s) taken.

Even though the responsibility for batch acceptance or rejection lies with the head of the quality control unit, the help of the validation committee should prove useful in reviewing the process of OOS investigation and arriving at a recommendation for action taken.

CLEANING VALIDATION

According to 21 CFR Sect. 211.67, Equipment Cleaning and Maintenance of cGMP regulations (3), equipment and utensils should be cleaned, maintained, and sanitized at appropriate intervals to prevent malfunction or contamination that would alter the safety, identity, strength, quality, or purity of the drug product. Written procedures shall be established and followed for cleaning and maintenance of equipment. These procedures shall include, but are not limited to the assignment of responsibility for cleaning and maintaining equipment; maintenance, cleaning, and sanitizing schedules where appropriate; description in sufficient detail of methods, equipment, and materials used in cleaning and maintenance operations, and the methods of disassembling and reassembling equipment as necessary to assure proper cleaning and maintenance; removal or obliteration of previous batch identification, protection of clean equipment from contamination prior to use; and inspection of equipment for cleanliness immediately before use.

Records shall be kept of maintenance, cleaning, sanitizing, and inspection.

The objective of cleaning validation of equipment and utensils is to reduce the residues of one product below established limits so that the residue of the previous product does not affect the quality and safety of the subsequent product manufactured in the same equipment.

According to 21 CFR Sect. 211.63, Equipment Design, Size, and Location, of cGMP regulations (3), equipment used in the manufacture, processing, packing, or holding of a drug product shall be of appropriate design, adequate size, and suitably located to facilitate operations for its intended use and for its cleaning and maintenance. Some of the equipment design considerations include type of surface to be cleaned (stainless steel, glass, plastic), use of disposables or dedicated equipment and utensils (bags, filters, etc.), of stationary equipment (tanks, mixers, centrifuges, presses, etc.), of special features (clean-in-place systems, steam-in-place systems), and identifying the difficult-to-clean locations on the equipment (so-called hot spots or critical sites).

The specific cleaning procedure should define the amounts and the specific type of cleaning agents and/or solvents used. The cleaning procedure should give full details as to what is to be cleaned and how it is to be cleaned. The cleaning method should focus on worst-case conditions, such as highest-strength, least-soluble, most difficult to clean formulations. Cleaning procedures should identify the time between processing and cleaning, cleaning sequence, equipment dismantling procedure, need for visual inspection, and provisions for documentation.

The choice of a particular analytical method (HPLC, TLC, spectrophotometric, total organic carbon (TOC), pH, conductivity, gravimetric, etc.) and sampling technique chosen (direct surface by swabs and gauze, or by rinsing) depends on the residue limit to be established, based upon the sampling site, type of residue sought, and equipment configuration (critical sites vs. large surface area) considerations. The analytical and sampling methods should be challenged in terms of specificity, sensitivity, and recovery.

The established residue limits must be practical, achievable, verifiable, and assure safety. The potency of selected drug and presence of degradation products, cleaning agents, particulates and microorganisms should be taken into consideration.

The following residue limits have been suggested: not more than (NMT) 10 ppm or NMT 0.001% of the dose of any product appears in the maximum daily dose of another product and no residue visible on the equipment after cleaning procedures have been performed.

PHARMACEUTICAL EXCIPIENTS

Pharmaceutical Excipients are components of finished drug products and site active components are recognized in the USP/NF. A list of key excipients for solid dosage forms is given:

Diluents, Fillers, and Binders:

- Calcium phosphate, dibasic
- Dextrates
- Dextrin
- Lactose (anhydrous, fast flow)
- Mannitol
- Starch (corn)
- Sugar, compressible

Tablet Disintegrants:

- Cellulose, microcrystalline
- Croscarmellose sodium
- Crospovidone
- Sodium starch glycolate
- Starch, pregelatinized

Tablet and Capsule Lubricants:

- Magnesium stearate
- Mineral oil, light
- Polyethylene glycol
- Sodium stearyl fumarate
- Stearic acid, purified
- Talc
- Vegetable oil, hydrogenated

Other Excipients:

- Carboxymethylcellulose sodium
- Cellulose acetate phthalate
- Ethylcellulose
- Hydroxypropyl cellulose
- Hydroxypropyl methylcellulose
- Hydroxypropyl methylcellulose pathalate
- Methacrylic acid copolymer
- Polysorbates
- Polyvinyl acetate phthalate
- Povidone
- Sodium lauryl sulfate

ACTIVE PHARMACEUTICAL INGREDIENTS (API)

A chemical is considered to be an API if it is intended for medicinal purposes. Regulatory agencies however, place greater emphasis and priority on the manufacture and validation of APIs than UPS/NF excipients.

According to Sect. 501 (a)(2)(b) of the Food, Drug, and Cosmetic (FD&C) Act, all drugs must be manufactured, processed, packed, and held in accordance with cGMPs. No distinction is made between APIs and finished drug products.

Elements common to both APIs and finished drug products include facilities and equipment qualification (IQ/OQ, and PQ), cleaning validation, validation of water supplies, microbial limits for nonsterile material, manufacture of sterile and pyrogen-free material, in-process blending and mixing, analytical methods validation, laboratory controls and in-process testing, change control procedures and revalidation, reprocessing, packaging and labeling, and stability testing.

Process

There are four primary processes used in the manufacture of APIs. They are chemical synthesis, fermentation, extraction, and purification. A flow diagram (Fig. 3) and a description of the chemistry involved are helpful in defining the process. The process description should include appropriate parameters, such as charging quantities or volumes of reactants or solvents, reaction times, temperatures, pressures, etc. Critical processing steps and critical operating parameters should be maintained to ensure batch-to-batch consistency, product yield, and quality.

Where in the chain of unit operations (chemical process) does API validation start? As long as key intermediates are made in the plant, they and their reaction and processing steps should be subjected to an appropriate cGMP and process qualification-validation program. A key intermediate is defined as an intermediate in which an essential molecular characteristic, usually related to stereochemical configuration, is introduced into the final API structure (moeity).

Physical Characteristics

Besides purity (chemical potency), the physical characteristics and properties of the API are extremely important to the end user (drug product manufacturer). Characteristics such as crystal morphology, particle size and shape, bulk density, melting point, optical rotation, etc., have a profound effect upon the final drug product and its performance and stability. In addition to the reaction or extraction step, crystallization, milling, and blending unit operations must be subject to qualification and validation.

Impurity Profile

The USP permits up to 2% of ordinary nontoxic impurities. However, impurities above 0.1% should be

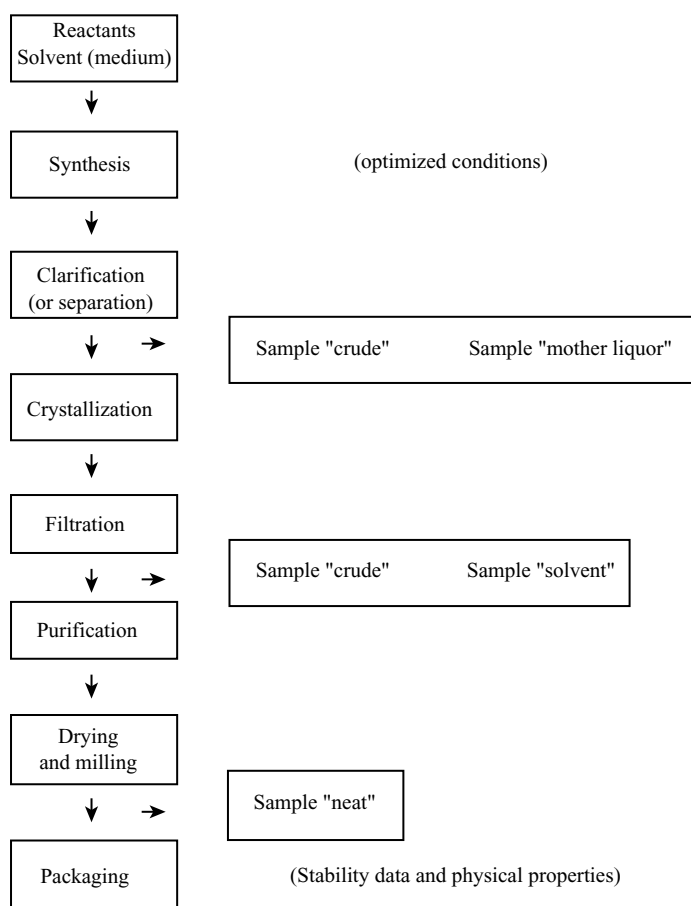

Fig. 3 Manufacture of active pharmaceutical ingredients (APIs).

fully characterized and quantified. Impurities may include starting materials, by-products, intermediates, degradation products, reagents, catalysts, heavy metals, electrolytes, filter aids, and residual solvents. Known toxic impurities must be held to a tighter standard, i.e., below 0.1%.

The ISO quality standards series

The ISO 9000 Series was developed in 1987 by the International Organization for Standardization (ISO) in Geneva, Switzerland. It is a comprehensive set of management standards governing the operation of quality assurance to help develop and document a quality system that is useful for individual companies.

The ISO 9000 Quality Management and Quality Assurance Standards, Guidelines for Selection and Use, provide basic definitions and concepts and explain how to use the rest of the series (9001, 9002, 9003, and 9004).

The ISO 9001 Quality System—Model for Quality Assurance in Design and Development provides for quality assurance in the areas of design, installation, servicing,

development, and production. It is useful primarily for companies that design and develop their own products.

The ISO 9002 Quality System—Model for Quality Assurance in Production, Installation and Service applies to manufacturers, distributors, and service vendors whose products have been designed and serviced by a subcontractor. Such companies are exempt from design control requirements. Both ISO 9001 and ISO 9002 are directly applicable to cGMPs. The connection between the two independent systems is shown in Table 5. Except for language, shades of meaning, and stresses the documents are similar.

The ISO 9003 Quality Systems—Model for Quality Assurance in Inspection and Testing, designed for testing laboratories and equipment distributors only requires conformance to final inspection and testing procedures.

The ISO 9004 Quality Management and Quality Systems Elements—Guidelines provide standards and guidelines for quality management planning and implementation.

VETERINARY DOSAGE FORMS

J. Desmond Baggot

Monash University, Parkville, Victoria, Australia

INTRODUCTION

Veterinary dosage forms are drug preparations designed for use in, or topical application to, one or more species of domestic animal and/or other species of veterinary interest. Although the majority of veterinary dosage forms contain the same drugs as human dosage forms, some veterinary preparations contain drugs that are not widely used in humans. Examples include benzimidazole anthelmintics, macrolide endectocides, salicylanilide flukicides, synthetic pyrethroids, chloramphenicol derivatives, α_2 -adrenoceptor agonists (sedative–analgesics), and antagonists. The converse applies to some classes of pharmacological agent (e.g., benzodiazepine derivatives, tricyclic antidepressants) because of limited clinical indications for use in animals. Veterinary pharmacology differs from human pharmacology both in the diversity of species of interest and in the emphasis placed on the various classes of drug. Some types of dosage forms are suitable for use in humans and certain animal species. They include parenteral solutions (although the concentration of the drug, the nature of the vehicle, and other constituents of the preparation must be considered); conventional tablets and capsules (amount of the drug relative to dosage requirement must be considered); oral solutions and suspensions (pediatric preparations are generally appropriate for administration to small animals, especially cats); and conventional ophthalmic preparations. Sustained-release tablets and controlled-release transdermal drug-delivery systems designed for use in humans could be used in medium to large breeds of dog. It is because of the unique physiological characteristics of each species, or closely related group of species, and the variation among species in the dose–effect relationship of pharmacological agents that veterinary dosage forms of drugs are required. Veterinary dosage forms designed specifically for use in certain animals species include long-acting parenteral dosage forms of antimicrobial agents for intramuscular injection, oral pastes containing antimicrobial agents or anthelmintics for horses, granules containing nonsteroidal anti-inflammatory drugs or anthelmintics for addition to the feed for horses or pigs, respectively, modified-release ruminal boluses containing anthelmintics for cattle or sheep,

intramammary antimicrobial preparations for cows, preparations containing ectoparasiticides for topical application to various species, and darts containing sedative drugs for capture and restraint of exotic animal species. The avoidance of drug residues in tissues and animal products (milk and eggs) is a regulatory requirement of veterinary preparations administered to food-producing species.

VETERINARY DRUGS

Although the majority of drugs available as veterinary dosage forms were initially developed for use in humans, based on experimental findings in laboratory animals, some drugs have been developed specifically for veterinary use. Anthelmintics and ectoparasiticides/insecticides are primarily veterinary drugs. Some anthelmintics (e.g., ivermectin, mebendazole, albendazole, pyrantel, piperazine, levamisole, praziquantel, bithionol) have been adopted for the treatment of parasitic infections in humans. Most ectoparasiticides are exclusively veterinary drugs. Some antimicrobial agents within certain classes, which include sulfonamides, fluoroquinolones, macrolides, chloramphenicol derivatives, and carboxylic ionophores, are available only for use in animals. Relatively few pharmacological agents were initially developed as veterinary drugs, although some drugs have indications for use in animals that do not apply to humans (Table 1). Other pharmacological agents have largely become veterinary drugs by virtue of their clinical efficacy in animals and replacement by alternative drugs for use in humans. Examples include phenylbutazone, quinidine, phenobarbital, and thiopental.

Steroid (sex) hormones, gonadotrophins, gonadotrophin-releasing hormones (synthetic forms and GnRH analog), and synthetic prostaglandins ($F_{2\alpha}$ type or analog) are used in female animals (cows, ewes, sows, and mares) to regulate various stages of the estrous cycle, whereas synthetic prostaglandins may be used to induce parturition. Melatonin, a modified-release dosage form implanted subcutaneously behind the ear of ewes, is used to stimulate the onset of cyclical ovarian activity. Progestogens are used to synchronize estrus in groups of animals or to enable

Table 1 Some pharmacological agents that are used exclusively in animals

Drug	Classification	Clinical indications
Xylazine	α_2 , (α_1)-adrenoceptor agonist	Sedation; analgesia preanesthetic medication
Yohimbine	α_2 , (α_1)-adrenoceptor antagonist agonist	Xylazine reversal
Detomidine	α_2 -adrenoceptor agonist	Preanesthetic medication
Atipamezole	α_2 , (α_1)-adrenoceptor antagonist	Detomidine reversal
Acepromazine	Phenothiazine-derivative tranquilizer	Preanesthetic medication; sedation
Etorphine–Acepromazine	Potent opioid agonist-PTZ-derivative tranquilizer	Neuroleptanalgesia
Diprenorphine	Opioid antagonist	Etorphine reversal
Droperidol–Fentanyl	Butyrophenon μ -opioid agonist	Neuroleptanalgesia
Azeperone	Butyrophenone	Preanesthetic medication; Behavior modification (pigs)
Alfadolone–Alfaxalone	Steroid anaesthetic(contraindicated in dogs)	Anesthesia
Flunixin	Cyclo-oxygenase inhibitor	Anti-inflammatory; analgesia; antipyresis
Metamizole (Dipyrone)	Cyclo-oxygenase inhibitor	(“Similar” to other NSAIDs)

prediction of the onset of estrus. On removal of the progestogen source (intravaginal device for cows and ewes; added to feed for sows and mares), the negative feedback effect on the pituitary and hypothalamus is terminated, and estrus is initiated. Progestogens (medroxy-progesterone, megestrol, proligestone), generally administered by subcutaneous injection, are used to suppress ovarian activity (estrus) in dogs and cats, whereas altrenogest (added to feed) is used to suppress estrus in cycling mares or to synchronize estrus in gilts and sows.

Monensin, a carboxylic ionophore antibiotic, is available as a premix (for addition to feed) used for the prevention of coccidiosis caused by *Eimeria* spp. in broiler chickens. Turkeys over 16 weeks of age, guinea fowl, and other game birds should not be given access to monensin-containing feed. Monensin is used as a production enhancer (improves feed conversion efficiency and growth rate) in beef cattle and dairy heifers up to the time of first service. It is available for use in cattle as a premix (sodium salt) for addition to the feed and as a modified-release ruminal bolus. The oral LD50 (mg/kg) of monensin differs among species: horses, 2–3; sheep, 12; pigs, 16; cattle, 22; and chickens, 200. Extreme care should be taken not to feed cattle, pig, or poultry rations or supplements to horses and to avoid accidental contamination in feedmills. Steroid hormone-growth promoters (bovine somatotropin, porcine somatotropin, bovine growth hormone-releasing factor) are available for use as production enhancers in some countries, whereas in others (European Union member states), their use is banned. The properties of somatotropins and the dosage forms that have been studied were comprehensively reviewed by Foster (1). The use of β_2 -adrenoceptor agonists such as clenbuterol for production enhancement in cattle is illegal.

Some antidotal substances used in the treatment of plant or heavy metal toxicity in animals could be considered veterinary drugs. They include methylthionium chloride (methylene blue), sodium nitrite, sodium thiosulfate, ammonium molybdate, and sodium calciumedetate. Phytomenadione (vitamin K₁) is indicated for the treatment of warfarin and coumarin poisoning in animals. The substances are present in sweet vernal grass *Anthoxanthum odoratum* and in spoiled sweet clover (*Melilotus officinalis* and *M. alba*) hay, and silage. Acetylcysteine and ascorbic acid are used concurrently in the treatment of acetaminophen (paracetamol) toxicity in cats. The acetylcysteine, which is administered by intravenous injection, serves as a precursor for glutathione replenishment, whereas ascorbic acid (administered intravenously or orally) reduces methemoglobin to hemoglobin. Feline hemoglobin is particularly susceptible to oxidative damage (methemoglobinemia). Atropine sulfate is widely used in animals for preanesthetic medication (although glycopyrronium is preferred in horses) and at a much higher dose (25 to 40 times the preanesthetic dose, 44 μ g/kg), often in conjunction with a cholinesterase-reactivating agent (pralidoxime mesilate), in the treatment of organophosphate toxicity.

This overview of veterinary drugs shows applications of these drugs in animals and how some aspects of veterinary and human pharmacology differ in their orientation.

CATEGORIZATION OF SPECIES

Even though mammalian species differ in physical characteristics (notably body weight) and behavior, they

possess the same body systems that perform generally similar physiological functions. There are, however, species-related adaptations that account for the uniqueness of each species. The character of the adaptations underlies the feasibility of extrapolating scientific information obtained in certain species (such as laboratory animals) to other species (domestic animals) and human beings. Because the pattern of quantifiable adaptations can be generally described mathematically, it is possible to make some predictions regarding interspecies extrapolation. The reliability of predictions on drug bioavailability and disposition depends on knowledge of both the anatomical and physiological similarities of and differences among the species of interest.

The anatomical arrangement of the gastrointestinal tract serves as a basis for broadly categorizing domestic animals as ruminant species (cattle, sheep, and goats) or monogastric species (horses, pigs, dogs, and cats). Consideration of dietary habit somewhat refines the categorization and enables the pattern of drug absorption to be explained as well as the potential interaction among commensal microbial flora in the digestive system and drugs, especially antimicrobial agents. Ruminant species are herbivores with a voluminous forestomach compartment in which microbial fermentation takes place continuously. Horses are monogastric herbivores with a small-capacity stomach and large-capacity colon where microbial digestion takes place. Dogs and cats are monogastric carnivores, whereas pigs are monogastric omnivores (similar to humans) fed a vegetable diet. Because the urinary pH reaction is determined primarily by the composition of the diet, the usual pH range differs among herbivorous species (pH 7.2–8.4) and carnivorous species (pH 5.5–7.0), whereas in omnivorous species, urinary pH can vary over a wide range (pH 4.5–8.2), but would be expected to be alkaline in pigs, whereas it is usually acidic in humans. Urinary pH influences the extent of reabsorption from the distal renal tubules and the half-life of weak organic acids and bases when a significant fraction (arbitrarily >20%) of the systemically available dose is eliminated by renal excretion.

The character of the female reproductive (estrous) cycle varies with the animal species in several respects, that include duration of cycle, length of estrus (sexual receptivity), and time of ovulation (Table 2) (2). In seasonal breeding species (mare, ewe, doe, and queen), the time of year during which estrous cycles occur is strongly influenced by the photoperiod. The mare and queen become anestrus in late autumn owing to decreasing daylight hours, and cycles are re-established with increasing daylight in early spring. The converse situation applies to ewes and does. The plane of nutrition can affect the onset of

estrous cycles in seasonal breeding species. The queen is unique among domestic animal species in that ovulation is induced by coitus. Pharmacological intervention at any stage of the reproductive cycle, whether it be to induce ovulation in mares, ewes, or cows or to suppress estrus or prevent ovum implantation in bitches or queens, is based on changing the plasma concentrations of the reproductive hormones that influence the particular process. To be successful, knowledge of the temporal pattern of the various hormone concentrations in plasma is essential.

Because avian and mammalian species differ in many respects, these distinct classes of animal should be considered separately. Avian species that are “farmed” include chickens, turkeys, ducks, geese, ostriches, guinea fowl, quail, and pheasants. The term poultry refers to farmed domestic fowl that, in common usage, includes chickens, turkeys, ducks and geese, whereas other farmed avian species are considered game birds. Application of the collective term poultry overlooks species differences in dosage requirements and drug residues in tissues as well as differences in susceptibility to toxicity of some drugs.

Birds (and reptiles) have a well-developed renal portal system that drains blood from the caudal portion of the body. Consequently, drugs administered parenterally in the lower extremities (hind limbs) of those species pass through the kidneys before entering the systemic circulation. This feature of blood flow to the kidneys provides the opportunity for first-pass excretion of water-soluble ionized drugs (e.g., β -lactam and aminoglycoside antibiotics) to occur.

Fish, reptiles (which include crocodiles and alligators), and amphibians are poikilothermic, i.e., cold-blooded animals. In contrast to homeothermic animals, the disposition of drugs in poikilothermic animals is influenced by environmental temperature. When applied to fish, the rate of drug elimination varies with the temperature of the water to which the fish are acclimatized. Studies of drug disposition in fish should generally be carried out at more than one water temperature, and whether fresh water or sea water is contained in the tank depends on the species of fish. A complication arises in the case of salmon for example, because adult salmon live in sea water but spawn and grow as fingerlings in fresh water.

DOSAGE FORMS AND ROUTES OF ADMINISTRATION

The type of dosage form, the route of administration, and site of injection of parenteral preparations depend on the animal species or group of related species (such as

Table 2 Average length of various stages of reproductive cycles of domestic animals

Species	Duration of estrus cycle	Length of estrus	Time of ovulation	Time fertilized ova enter uterus (after conception)	Time of implantation (after conception)	Type of placenta	Length of pregnancy
Mare ^a	21 days	5–6 days	Last day of estrus	3–4 days	30–35 days	Epitheliochorial	345 days
Cow	21 days	18 h	12 h after end of estrus	3–4 days	30–35 days	Epitheliochorial	280 days
Ewe ^a	17 days	36 h	30 h after beginning of estrus	3–5 days	15–18 days	Syndesmochorial	147 days
Doe ^a (goat)	20 days	40 h	30–36 h after beginning of estrus	4 days	20–25 days	Syndesmochorial	147 days
Sow	21 days	45 h	36–40 h after beginning of estrus	3–4 days	14–20 days	Epitheliochorial	113 days
Bitch	In estrus at 7–8 month intervals depending on breed	Proestrus, 9 days; estrus, 7–9 days	First or second day of estrus	5–6 days	15 days	Endotheliochorial	64 days
Queen ^a	16 days (nonbred) (pseudopregnancy lasts 36 days)	5–6 days	Induced 24–32 h after coitus	4 days	13 days	Endotheliochorial	65 days

^aSeasonally polyestrous. (Modified from Ref. 2.)

ruminant animals or poultry). The greatest differences relate to oral dosage forms and topical preparations. Whether a veterinary dosage form is intended for individual animal treatment or for administration/application to a large group of animals (herd or flock medication) should be decided before the development of a dosage form. Convenience of administration and cost of the drug preparation are foremost considerations in determining the use of a veterinary dosage form by animal owners.

GASTROINTESTINAL ABSORPTION

The anatomical arrangement of the gastrointestinal tract and associated digestive physiology govern the pattern of drug absorption. In pigs, dogs, cats, and humans, the plasma concentration profile after the administration of an oral solution or conventional (immediate-release) dosage form is generally similar in that it shows a reasonably well-defined single peak. Because the rate of gastric emptying differs among monogastric species and the anterior (upper) portion of the small intestine is the principal site of absorption, the time at which the peak plasma concentration occurs may vary. An effective pH value of 5.3 in the microenvironment of the intestinal mucosal surface, rather than the reaction of intestinal contents (average pH 6.6), is consistent with observations on the absorption of drugs that are weak organic acids or bases. Under normal conditions, weak acids with pK_a values above 3.0 and bases with pK_a values below 7.8 are well-absorbed from the small intestine (3). An alteration in the pH of the stomach or small intestine contents can markedly change the degree of ionization of drugs that are weak organic electrolytes (acids or bases). At pH values below the pK_a , weak acids exist primarily in the nonionized form, which is the moiety that can readily be absorbed; the converse applies to weak bases. Lipid-soluble neutral molecules (digoxin, chloramphenicol) and fluoroquinolones (amphoteric compounds) are well-absorbed in dogs, although the systemic availability of norfloxacin is much lower than that of enrofloxacin/ciprofloxacin or marbofloxacin. Because of their polar nature, aminoglycoside antibiotics are poorly absorbed from the gastrointestinal tract and must be administered parenterally in the treatment of systemic bacterial infections.

After the administration of a sustained-release oral dosage form, the duration of drug availability for absorption is limited by the sum of the residence times of the dosage form in the stomach and small intestine. This has been estimated to be 9–12 h in dogs. In the development of a sustained-release dosage form for use

in dogs, the aim is to provide an effective plasma concentration of the drug throughout the dosage interval (12 h) with an acceptable degree of fluctuation in steady-state concentrations. The latter is determined both by the half-life of the drug and the dosage interval (4). Suitable candidate drugs should have reasonably high oral bioavailability, which implies reliable absorption from the gastrointestinal tract and no more than partial inactivation by the first-pass effect unless active metabolites are formed, a half-life in the range of 4 to 6 h, and a relatively high potency but reasonably wide range of therapeutic plasma concentrations. Because of variation between dogs and humans in the oral bioavailability and the rate of elimination of most lipid-soluble drugs, those that would be suitable for formulating as sustained-release dosage forms often differ between the two species. Theophylline meets the criteria that make it suitable for formulating as a sustained-release oral preparation for administration to dogs. Of the sustained-release oral dosage forms that are commercially available, anhydrous theophylline in tablet form (200 and 300 mg) is preferred for use in dogs. This product has an oral bioavailability (theophylline) of 76%, and the dosage regimen (20 mg/kg administered at 12-h intervals) has been predicted to maintain plasma concentrations within the therapeutic range (6–16 $\mu\text{g/ml}$) with less fluctuation in peak-to-trough theophylline concentrations than other sustained-release dosage forms (5). The dosage regimen for the conventional dosage form (aminophylline tablets) is 10 mg/kg administered at 8-h intervals to dogs.

Other drugs of veterinary interest that have been formulated as sustained-release oral dosage forms include morphine, propranolol, quinidine, procainamide, and verapamil or diltiazem. Of these, sustained-release morphine sulfate (tablets, 15 mg) has the greatest potential for use in dogs over 10 kg body weight. The proposed dosage regimen, 1–2 mg/kg administered at 8- or 12-h dosage intervals, may be effective in the management of chronic pain (6). The sustained-release dosage form overcomes the shortcoming of conventional oral preparations of morphine, which is their short duration of action in dogs. Phenytoin is a likely candidate drug for formulating as a sustained-release dosage form because it would enable phenytoin to be used in dogs for the prevention/treatment of generalized tonic-clonic seizures (grand mal epilepsy). The average oral bioavailability of phenytoin administered as the conventional dosage form is 36%, the half-life in dogs is 3.5–4.5 h (dose-dependent), and the therapeutic range of plasma concentrations is 10–20 $\mu\text{g/ml}$. Oral bioavailability of phenytoin in humans is 90%, and the apparent half-life, which is dose-dependent, is 15–24 h. The slower elimination of phenytoin in humans obviates the

need for the development of a sustained-release dosage form.

Even though the horse is a monogastric species, the stomach has a small capacity (8.5% of the gastrointestinal tract) compared with that of the pig (29%) and the dog (62%). Expressed on the basis of volume capacity, the stomach of the horse, pig, and dog can hold 7–14, 5.5–7, and 3–8 L, respectively. The average pH value of gastric contents in horses is less acidic (pH 5.5; range, 4.5–6.0) than in other monogastric species (pH 3–4), and a substantial portion of the stomach lining is composed of stratified squamous epithelium. Under natural conditions of management, horses feed continuously. The fibrous component of the feed is digested primarily in the large intestine, although horses digest fiber less efficiently than do ruminant species. Microbial digestion of fibrous carbohydrates to volatile fatty acids and break down of undigested dietary protein to peptides and amino acids takes place in the large intestine. The combined capacity of the caecum and colon occupies approximately 55% of the gastrointestinal tract, and the pH of large intestinal contents is 6.6–6.8. Two unrelated features of the digestive system are that horses do not possess a gall bladder (similarly camelids and giraffes) and are unable to vomit. The temporal relationship between feeding and oral dosing can greatly influence the pattern of drug absorption. Because the systemic availability of most antimicrobial agents administered orally (paste formulations) or by nasogastric tube (aqueous suspensions) to horses is significantly decreased by feeding shortly before dosing, food should be withheld for up to 2 h after administration of an antimicrobial agent. Feeding horses close to the time of administering phenylbutazone in various oral dosage forms changed the pattern without altering the extent of absorption of the nonsteroidal anti-inflammatory drug (7). The availability of a drug for absorption from the small intestine of the horse, particularly when administered in

conjunction with or shortly after feeding, may be limited by adsorption to the ingested feed, especially hay. Under these circumstances, absorption may occur in two phases, initially (1–2 h after drug administration) from the small intestine and several (8–10) hours later from the large intestine (principal site) after microbial digestion of the fibrous material in feed (7, 8). The inadvertent contamination of horse feed with a feed additive premix approved for use as a production enhancer/growth promotant in cattle or pigs, may cause toxicity, even death, in horses.

The anatomical arrangement of the gastrointestinal tract distinguishes ruminant (cattle, sheep, and goats) from monogastric(horses, pigs, dogs, and cats) species (Table 3). The difference in digestive physiology between the two groups of species determines the types of oral dosage forms appropriate to administer and influences oral bioavailability of drugs. Susceptibility to ingested plant toxicity differs between ruminant and monogastric species. The volume capacity of the mature reticulorumen is 100–225 L in cattle and 10–25 L in sheep and goats and accounts for approximately 60% of the total capacity of the gastrointestinal tract. The forestomach contents vary from liquid to semisolid consistency, and the pH reaction is normally maintained within the range 5.5 to 6.5 owing to copious secretion of alkaline saliva (pH 8.2–8.4) particularly rich in bicarbonate and phosphate buffers but devoid of amylase. In addition to its buffering action, saliva has an antifoaming action that serves to prevent dietary bloat. Salivary secretion, at a daily rate of 100–190 L in cattle and 6–16 L in sheep, is essential for microbial digestion, which takes place continuously in the reticulorumen. Based on average values of saliva flow and volume of the rumen liquid pool, the turnover rate for reticulorumenal fluid was estimated to be 2.0/day for cattle and 1.1–2.2/day for sheep (9). Despite the stratified squamous nature of its epithelial lining, the rumen has considerable absorptive

Table 3 Relative capacity of components of digestive tract of domestic animal species

Component	Relative capacity (%)			Component	Relative capacity (%) (Sheep and Goat)
	Horse	Pig	Dog		
Stomach	8.5	29.2	62.3	Rumen	52.9
Small intestine	30.2	33.5	23.3	Reticulum	4.5
Cecum	15.9	5.6	1.3	Omasum	2.0
Large colon	38.4			Abomasum	7.5
		31.7	13.1		
Small colon and rectum	7.0			Small intestine	20.4
				Cecum	2.3
				Colon and rectum	10.4

capacity (10, 11). Because absorption takes place by passive diffusion, lipid-soluble drugs, whether neutral molecules or the nonionized form of weak organic acids or bases, may be absorbed from the rumen. The theoretical equilibrium distribution, expressed as concentration ratio, of weak organic acids and bases of different pK_a values between saliva (pH 8.2) or ruminal contents (pH range 5.5–6.5) and plasma (pH 7.4) is presented graphically (Fig. 1) (12).

Ruminal micro-organisms are capable of at least partially metabolizing some drugs (e.g., trimethoprim, chloramphenicol, nitroxylin, digitalis glycosides) either by hydrolysis or reduction, which would decrease the amount of drug available for absorption. Intraruminal biotransformation makes ruminant species susceptible to toxicity caused by ingestion of plants containing cyanogenic glycosides (cyanide poisoning) or accumulated nitrate (nitrite poisoning). Overuse of nitrogenous fertilizers contributes to the incidence of nitrite poisoning. Antidotal substances that are used (injected intravenously) to treat these toxicities are sodium nitrite, followed by sodium thiosulfate for cyanide poisoning and methylthioninium chloride (methylene blue) for nitrite poisoning. In ruminant species, in which chemical compounds can be

altered (activated or detoxified) by microbial action in the forestomach and in which the whole physiological tempo of the body is so dependent on ruminal activity, no pharmacological or toxicological investigation can be interpreted without full consideration of the basic diet and feeding regimen (13).

After comminution by rechewing and microbial digestion, the liquid component with suspended particles of reticuloruminal contents is “pumped” by the omasum (third compartment of the forestomach) into the abomasum (true stomach). During the two-stage transfer process, water and electrolytes are absorbed, and the size of particulate matter in the digesta is reduced. The abomasum, which accounts for approximately 4–5% of the capacity of the gastrointestinal tract in adult cattle and 7.5% of gastrointestinal capacity in sheep and goats, is the only compartment of the ruminant stomach that secretes digestive juices. Secretions from the fundic area of the abomasum contain hydrochloric acid, pepsin and, in suckling preruminant animals, rennin (a milk-coagulating enzyme). Mucus is produced by the columnar epithelial cells that line the abomasum. The pH reaction of abomasal contents does not vary much and is usually close to pH 3.0 (14).

Because of the large volume of reticuloruminal contents, a drug can attain only a low concentration in the reticulorumen, whether administered in solution, suspension, or solid dosage form. In dissolution of solid dosage forms, dilution in the large volume of fluid and binding to particulate matter would decrease the rate, but not necessarily the extent, of drug absorption. Lipid-soluble neutral molecules and the nonionized form of weak organic electrolytes, particularly organic acids, should normally be well-absorbed from the reticulorumen. When aspirin (pK_a 3.5) in a solid dosage form (60 g, which is equivalent to 3.9 g of oral bolus) was administered to cows, salicylate was slowly absorbed, and systemic availability was 50–70% (15). The 12-h dosage interval for aspirin in adult cattle is based on the rate of absorption rather than on the half-life of salicylate, which is 0.8 h.

Benzimidazole anthelmintics (albendazole, fenbendazole, oxfendazole, which is fenbendazole sulfoxide); probenzimidazoles (netobimin and febantel, which are metabolically converted to albendazole and fenbendazole, respectively); and salicylanilide flukicides (closantel, rafoxanide, oxclozanide) are administered as oral suspensions to ruminant animals. For anthelmintic drugs oral suspensions have an advantage over oral solutions in that the delayed availability of drug for absorption extends the duration of action. Reducing the level of feed intake (for 36 h before and 36 h after dosing) delays the onward passage of ruminal fluid with suspended matter from the reticulorumen to the abomasum and small intestine and

Fig. 1 Expected equilibrium distribution between saliva or rumen contents and plasma of acids and bases of differing pK_a . Concentration ratio is the ratio of the salivary or ruminal concentration to concentration free in the plasma, calculated separately for acids and bases, for saliva of pH 8.2 and rumen contents over a range of pH 5.5–6.5, assuming plasma is pH 7.4. (From Ref. 12.)

would allow more time for drug dissolution and absorption to occur. When the rate of onward passage of ruminal fluid was decreased, by temporarily reducing feed intake, in sheep, the systemic availability of oxfendazole was increased (16). The systemic availability of rafoxanide and triclabendazole, administered as oral suspensions, was higher in housed lambs fed hay and concentrates than in lambs grazing on pasture (17). The effect of dietary regimen/composition on systemic availability of the flukicides could be attributed to the time allowed for dissolution and absorption of the drugs.

Closure of the reticular groove would allow an oral solution to flow directly from the cardiac orifice of the rumen into the abomasum, bypassing the rumen. Spontaneous closure of the groove occurs reflexly in some animals although at least partial closure can be chemically induced. Should rapid absorption of a drug (such as a nonsteroidal anti-inflammatory drug) from the gastrointestinal tract be desired, an oral solution of the drug could be administered immediately after inducing closure of the reticular groove. This can be achieved generally in cattle by administering orally a solution containing sodium bicarbonate and in sheep by administering orally a copper sulfate solution or injecting intravenously a dose (0.3 U/kg) of lysine-vasopressin. Closure of the reticular groove would be unwanted in the case of an oral liquid, such as dimeticone emulsion or poloxaline, used to treat frothy bloat in cattle. In young ruminant animals, reflex closure of the reticular groove, induced by suckling, allows milk to flow directly to the abomasum.

Advantage can be taken of the anatomical arrangement of the forestomach of ruminant animals by administering a modified-release ruminal bolus that will remain lodged in the reticulorumen for a prolonged period. Slow-release ruminal boluses containing trace elements (cobalt oxide, copper oxide, cobalt and copper in sodium phosphate glass matrix, and selenium as sodium selenate) are commercially available for administration to cattle or sheep, and the compound ruminal bolus can be administered to farmed adult deer. Controlled-release ruminal boluses containing certain anthelmintic drugs (ivermectin, fenbendazole, oxfendazole, morantel) or the production enhancer monensin are available for oral administration, using a specialized delivery device, to beef cattle within a specified range of body weight (100–400 kg). These systems are designed either to continuously release the drug into ruminal fluid for a prolonged period (generally 120–140 days) or to intermittently release pulse doses (oxfendazole bolus) at a predetermined interval (approximately 3 weeks). This interval generally coincides with the prepatent period of the major gastrointestinal trstrongylids of cattle (18). Controlled-release ruminal boluses that continuously

release ivermectin, fenbendazole, or morantel into ruminal fluid are available for use in beef cattle, whereas controlled-release boluses that deliver albendazole or ivermectin over a period of 100 days are available for use in sheep (35–65 kg in body weight). The delivery systems are retained in the reticulorumen at least throughout the entire period of drug release. The retention of oral controlled-release drug delivery systems designed for use in humans is limited by gastric emptying time, which can be up to 12 h (19).

FIRST-PASS EFFECT

Having traversed the gastrointestinal mucosal barrier, drug molecules are conveyed in hepatic portal blood to the liver, where they are subjected to the first-pass effect before entering the systemic circulation. The first-pass effect applies to all animal species and, owing to the generally higher capacity of the liver of herbivorous species (ruminant animals and horses) to metabolize lipid-soluble drugs by microsomal oxidative reactions, is likely to decrease the systemic availability of these drugs to a greater extent in herbivorous than in nonherbivorous species (dogs, cats, pigs, humans). In ruminant species (cattle, sheep, goats) and *Equidae* (horses, ponies, donkeys), triclabendazole, administered as an oral suspension, is converted by hepatic first-pass metabolism to triclabendazole sulfoxide (active metabolite), which is subsequently converted to the sulfone (inactive) metabolite. In many species, the first-pass effect can substantially reduce the systemic availability of orally administered lipid-soluble drugs that undergo extensive biotransformation in the liver (e.g., diazepam, propranolol, verapamil). Although presystemic metabolism occurs primarily in the liver, it can also take place in the small intestinal mucosa during the absorption process. Some drugs that show incomplete systemic availability after oral administration to dogs are listed in Table 4. Presystemic metabolism in the liver is responsible for incomplete systemic availability of the majority of these drugs. The oral bioavailability of digoxin was enhanced in humans when the drug was administered as an aqueous alcoholic solution in gelatin capsules rather than in tablet form, even though the tablets had a satisfactory dissolution rate (20–22). In a similar manner, increased relative bioavailability, based on comparison of areas under the plasma concentration–time curves of flufenamic acid, was achieved in dogs when the drug was administered in soft rather than hard gelatin capsules; the average increase was 34% (23). In both instances, the higher oral bioavailability was attributed to physicochemical factors brought into play by adjuvants in the soft gelatin capsules. The influence that

Table 4 Systemic availability of some orally administered drugs in dogs

Drugs (dosage form)	Dose (mg/kg)	Systemic availability (%)	Site of metabolism/ other factor
Phenobarbitone (tablet)	10	86–96	Liver

formulation, or rather dosage form, can have on the systemic availability of an orally administered drug was shown in horses given racemic ketoprofen (2.2 mg/kg). The systemic availability of the S(+)- and R(–)-enantiomers was 54.2 and 50.5%, respectively, after administration of micronized racemic ketoprofen powder in hard gelatin capsules to horses with restricted access to feed. When ketoprofen powder from the same batch was administered as an oil-based paste, systemic availability of the S(+)- and R(–)-enantiomers was 5.75 and 2.7%, respectively, regardless of the feeding schedule (24). To avoid hepatic first-pass metabolism, glyceryl trinitrate (nitroglycerin) is formulated in a variety of dosage forms, which include parenteral solution, spray for sublingual application, sustained-release tablet, and transdermal therapeutic systems, for use in humans, and as an ointment for topical application to dogs (cardiogenic pulmonary edema) or horses (acute laminitis). Sublingual administration avoids the first-pass effect, but it is not feasible to administer solid dosage forms by this route to animals.

Although the first-pass effect is a major source of species variation in systemic availability of orally administered drugs that undergo extensive hepatic metabolism, another

important source of variation is metabolism by ruminal microorganisms. Some drugs (nitroxylin, chloramphenicol, digitalis glycosides) are metabolized in the rumen to such an extent that parenteral administration is required for clinical efficacy.

An advantage of rectal over oral administration of lipid-soluble drugs is partial avoidance of the first-pass effect. The extent to which the first-pass effect is avoided appears to be less in dogs than in humans. Because venous drainage of the rectum of the horse, unlike in the humans and dog, appears to be substantially into the hepatic portal vein, minimal avoidance of hepatic first-pass metabolism of drugs absorbed from the rectum could be anticipated in horses.

ORAL DOSAGE FORMS

The oral route of drug administration is safer than parenteral routes and avoids tissue irritation at injection sites. However, wide variation, both inter- and intraspecies, in systemic availability is a feature of orally

administered drugs. The convenience of oral drug administration depends on the species of animal and the dosage form of the drug. To facilitate drug administration and take into account the anatomy and physiology of the digestive system and the average body weight of the various animal species, the requirements of oral dosage forms differ among species. Consideration must be given to size of the total dose (amount of drug) to be administered and oral bioavailability in the animal species.

Oral dosage forms available for administration to animals include oral solutions, liquids, suspensions, gels, pastes, capsules, tablets, ruminal boluses, powders and granules for addition to feed, soluble powders for addition to drinking water or fish medicating baths, and premixes for addition to feed for livestock or poultry. The type of dosage form is determined by the solubility and physicochemical properties of the drug, the species of animal for which the dosage form is intended, and whether a reasonably rapid onset or a prolonged duration of effect is required. Liquid dosage forms (oral solutions and liquids) provide readily available drug for absorption, particularly in monogastric species. Oral liquids, such as dimeticone emulsion and poloxaline (anionic surfactant), are used for the treatment of frothy bloat in cattle. An oral liquid containing propylene glycol (glucose precursor) for addition to drinking water or for preparation of an oral solution is indicated for adjunctive treatment of ketosis in cattle and sheep. Aqueous suspensions are administered by nasogastric tube to horses, by mouth (as a drench) to ruminant animals and by mouth (sometimes with the aid of an oral syringe) to dogs and cats. Oral pastes and gels are semisolid dosage forms supplied in preloaded calibrated syringes designed for convenience of drug administration to horses by their owners. The formulation of a paste must be such that it is syringeable over a wide range of ambient temperatures, is moderately tenacious so that it will adhere to the tongue, and is tasteless or suitably flavored (mint or apple flavor appears to be preferred by horses). Classes of drugs that could be formulated as oral pastes or gels for administration to horses include anthelmintics, nonsteroidal anti-inflammatory drugs, and some antimicrobial agents. Application of an anthelmintic paste, at the appropriate dose of the drug, to the distal forelimbs of cats is a convenient alternative to oral administration of a tablet or capsule. Solid dosage forms must undergo disintegration and dissolution in the stomach before absorption of the drug can occur. Drug release from solid dosage forms delays the rate of absorption compared with that from an oral solution. With regard to the quality of solid dosage forms, capsules offer an advantage over tablets in that the particle size and distribution of the active ingredient are rarely altered by the capsule-filling process, whereas

physical stresses (compression and heat) are imposed in the manufacturing process of tablets. In addition, capsules provide more rapid dissolution than do conventional tablets of the same active ingredient. The pattern of release of coated pellets or granules is more predictable when packed in capsules than compressed into tablets. Capsules, however, are generally more expensive than tablets containing the same drug. Because of the higher manufacturing cost, soft gelatin capsules should probably be used in preference to hard gelatin capsules only when the fill is liquid or bioavailability of the drug is significantly superior. An encapsulated active ingredient, until released, would be protected against metabolism by ruminal micro-organisms and/or chemical degradation in the ruminal environment. Encapsulation of insect development inhibitors (e.g., diflubenzuron) or insect growth regulators (e.g., methoprene) has potential application in cattle. These substances interfere with the metamorphosis and reproductive capacity of arthropod parasites, many of which breed in cattle dung. Dichlorvos, an organophosphorus compound with activity against gastrointestinal nematodes including whipworms (*Trichuris* spp.), is incorporated into polyvinyl chloride resin pellets (plasticization) for addition to the feed for pigs or canned food for dogs. This dosage form protects dichlorvos from hydrolytic degradation and provides slow release into the gastrointestinal tract, which greatly increases the margin of safety of the drug.

A sustained-release dosage form provides an initial amount of drug sufficient to provide a desired therapeutic concentration and continuously releases the drug at a constant (zero-order) rate for an extended period. The margin of safety of the drug is an important consideration, because sustained-release dosage forms contain a large amount of drug and the potential exists for "dose-dumping" with resultant toxicity. For drugs with half-lives in the range of 4 to 6 h, sustained-release dosage forms could provide a dosage interval of 12 h in dogs or 24 h in horses. Very few sustained-release preparations have been developed for use in either species. This type of dosage form has to be swallowed intact.

Controlled-release ruminal boluses are designed either to continuously release drug (an anthelmintic or production enhancer) at a constant rate for a prolonged specified period or to intermittently deliver pulse (usually five) doses at predetermined intervals. Each product is designed for use in either cattle or sheep within a specified range of body weight. Retention of orally administered controlled-release systems in the reticulorumen is dependent on either density or geometry of the system. The ivermectin (Ivomec) ruminal bolus, designed for use in cattle between 100 and 400 kg body weight,

contains 1.72 g of ivermectin that is continuously released into ruminal fluid at a constant rate (12.5 mg/day) over a period of 135 days. The bolus is a cylindrical device that consists of an outer semipermeable membrane enclosing a metal density element at one end, an osmotic energy source at the other end, and a formulation containing the drug in the center. The osmotic energy source is composed of a tablet containing a polymeric salt mixture. Absorption of water through the semipermeable membrane causes expansion of the tablet, which drives the ivermectin wax formulation through the exit port (channel) in the density element (25) (Fig. 2a). The

fenbendazole ruminal bolus (Panacur), designed for use in cattle between 100 and 300 kg body weight, contains 12 g of the anthelmintic which, is continuously released into ruminal fluid over a period of up to 140 days. Release of fenbendazole is controlled by the erosion of two magnesium alloy tubes; each tube contains five tight-fitting cylindrical tablets (6 g of fenbendazole). The magnesium alloy tubes are protected from the ruminal contents by a series of close-fitting rigid plastic rings; the central ring connects both tubes. The bolus is completely biodegradable and leaves no residual device in the forestomach (26). The morantel tartrate (Paratect Flex) ruminal bolus, designed for use in cattle over 100 kg body weight, contains 11.8 g of morantel base. The bolus consists of a drug-impregnated polymer packaged in a cylindrical trilaminar cartridge. Release of the drug (approximately 150 mg/day) takes place by diffusion through the semipermeable membrane into ruminal fluid over a period of at least 90 days. There is no withdrawal period associated with the use of the morantel tartrate trilaminar bolus because the combination of poor absorption and first-pass hepatic metabolism makes systemic availability of morantel exceedingly low. The Captec, also known as the Laby (27), device is a controlled-release ruminal capsule designed for use in sheep within a specified range of body weight that continuously releases the anthelmintic contained within, either albendazole (32.5 mg/day) or ivermectin (1.6 mg/day), over a period of 100 days. The device consists of a polypropylene barrel with a spring-loaded plunger at the closed (top) end and an orifice (series of perforations) at the base (Fig. 2b). A pair of polypropylene wings attached to the top of the barrel is secured in a folded position (compressed configuration) by water-soluble tape to enable oral administration. The barrel is loaded with tablets containing the anthelmintic, either albendazole (3.85 g) or ivermectin (160 mg). After administration of the ruminal capsule, the tape securing the pair of wings dissolves, and the wings open to a predetermined angle (expanded configuration) that prevents both regurgitation and reticulo-omasal passage. The rate of drug release is determined by a combination of factors that include the formulation of the tablets, the diameter of the orifice, and the pressure exerted on the tablets by the plunger. The ruminal fluid bathing the orifice of the device brings about dissolution of the tablets.

The modified-release ruminal bolus containing oxfendazole, designed for use in cattle in the body weight range of 200 to 400 kg, delivers pulse doses (1.25 g) at 3-week intervals over a period of 105 days (18). The bolus containing five tablets (Autoworm 5) releases the first dose at 21 days after administration whereas the bolus

Fig. 2 (a) IVOMEC schematic; (b) captec schematic.

containing six tablets (Autoworm 6) releases the first dose on the day of administration.

Drugs in powder form or prepared granules can be added to the feed for pigs. Shortcomings associated with this method of administration include uncertainty as to the amount of drug (dose) ingested and interanimal variation in oral bioavailability. The drug must have a wide margin of safety and be palatable in the feed and, importantly, the animal must be feeding. Inappetence or indifference to feeding is a usual feature of illness in animals. Addition to feed, often referred to as top dressing of feed, is generally an unreliable method of drug administration to horses. However, the packaging of powders or granules in unit dose sachets provides convenience of drug administration for owners when the number of animals to be dosed is small. Unit dose sachets must be prepared on an individual species basis because the dose level (mg/kg) may differ among species, and the average body weight range of domestic animal species differs by approximately 200-fold. Soluble salts of drugs in prepared solutions or powder form can be administered to poultry and other farmed avian species by addition to drinking water or to fish by addition to the water in a medicating bath of known volume capacity. Sachets containing various trace elements (cobalt, copper, iodine, selenium) for addition to drinking water delivered by dispenser are available for the correction of mineral deficiencies in cattle. The mineral content of each sachet suffices for 25 cattle for a period of 7 days. Several factors to consider in the design of premix formulations and to ensure their satisfactory mixing in bulk feed are addressed in detail by Klink et al. (28). Premixes must always be diluted to the approved use level, usually parts per million (ppm) [g/tonne (feed) or mg/L(water)], for the animal species.

INTRAMUSCULAR INJECTION

Intramuscular injection is a commonly used route for drug administration in animals. This route offers convenience in that it is easy to apply and, because a sizeable proportion of veterinary parenteral preparations are formulated as long-acting dosage forms, either a single dose may suffice or a long dosage interval can be used. There are, however, a number of factors to consider before choosing this route of administration. They include the purpose for administering the drug, the acceptable time interval between drug administration and onset of the desired effect, the suitability of available parenteral preparations for use in the particular animal species, the withdrawal period(s) in food-producing animals, and the cost of the drug preparation

for the anticipated course of treatment. The suitability of a parenteral preparation for use in a particular species primarily depends on the formulation of the preparation. Significant formulation variables include the concentration of drug in a preparation, which determines the volume to be injected, the nature of the vehicle and other ingredients (solubilizers, preservatives), and the likelihood of causing irritation at the injection site. The horse is the least tolerant of domestic animal species to injection-site irritation, and drugs in oily vehicles should never be administered by injection to horses.

Whereas the formulation of a preparation determines the pattern of absorption and influences systemic availability of the drug, the volume of the preparation deposited in muscle and the vascularity of the injection site determines the rate of absorption. The barrier to absorption is the capillary endothelium, which most drugs readily penetrate by passive diffusion, although small water-soluble molecules may enter capillaries by bulk flow through intercellular "pores" in the endothelial membrane. Aqueous channels (pores) in the capillary endothelium are approximately 10-fold larger in diameter (40–80 Å) than those in the intestinal epithelium. Polar drugs such as aminoglycoside antibiotics are rapidly and completely absorbed from intramuscular injection sites, whereas they are very poorly absorbed from the gastrointestinal tract when the epithelial membrane is intact. Drug absorption from intramuscular injection sites is generally assumed to be a first-order process. However, this assumption may not be entirely valid, particularly during the initial stage when absorption may obey zero-order (nonlinear) kinetics. Local and systemic factors that influence the rate of absorption seldom remain constant throughout the absorption process. Increased blood flow to skeletal muscle at the site of injection promotes absorption, whereas the administration of a drug that causes local vasoconstriction or the presence of a disease state that decreases skeletal muscle perfusion delays absorption. Deposition of the injected preparation between muscle masses (intermuscular) or in adipose tissue and the injection of a preparation that causes tissue irritation or precipitation of the drug at the injection site produce an erratic pattern of absorption that is reflected in the plasma concentration profile of the drug.

The site of intramuscular injection can affect the plasma concentration profile and bioavailability of a drug, particularly when a long-acting preparation is administered. The variation in the pattern of absorption can be attributed to regional differences in blood flow to skeletal muscles and in absorptive surface area. In cattle and goats, intramuscular injection in the lateral neck provides superior absorption to injection in the buttock

(*M. semitendineus*) and thigh muscle (*M. quadriceps femoris*), respectively, or subcutaneous injection in the lateral neck. In pigs, the lateral neck should always be used as the site for intramuscular injection of parenteral preparations. The reasons for selecting this site include better absorption than in other sites, less residual drug at the injection site, and avoidance of damage to the carcass. In dogs and cats, the quadriceps muscle mass is the preferred site for intramuscular injection, which should be performed slowly, of parenteral preparations. After the injection of procaine penicillin G (20,000 IU/kg) at various intramuscular sites and subcutaneously in the cranial part of the pectoral area in horses, the peak plasma concentration and systemic availability of penicillin G were highest when the long-acting preparation was injected i.m. in the neck region (*M. serratus ventralis cervicis*). This was followed, in descending order of injection site, by *M. biceps* > *M. pectoralis* > *M. gluteus*, or subcutaneously (Fig. 3) (29). The intramuscular injection technique must ensure that inadvertent intravenous administration does not occur.

Potential disadvantages of intramuscular injection are the deposition of the preparation in adipose tissue or intermuscular fascial planes and the production of tissue damage with persistence of drug residue at the site of injection (30–32). Tissue damage is more likely to be caused by constituents of the formulation than the drug substance *per se*. Useful antemortem methods of assessing the extent of tissue irritation and the rate of resolution at an intramuscular injection site include the echographical examination of the muscle tissue in the immediate vicinity of the injection site (33) and the monitoring of plasma creatine kinase (CK) activity (34, 35). These methods have

the distinct advantage of being applicable to the live animal. Should moderate to severe tissue damage be evident, the extent of the damage and precise nature of the lesion can be described on postmortem examination. The use of some tissue-damaging parenteral preparations in food-producing animals is unavoidable, and the specified withdrawal period(s) must be applied. The withdrawal period for a drug varies with the formulation of the dosage form (preparation), which should be administered only by the recommended route and may differ between animal species. Fish are ectothermic and their basal metabolic rate, which markedly influences the rate of elimination of drugs, varies with the temperature of the water to which they are acclimatized. It follows that withdrawal periods, stated in degree days, for drugs used in “farmed” fish (primarily by addition to feed or bath water) will vary with ambient water temperature.

In cats, puppies, and piglets, particular attention should be given to the drug concentration in parenteral preparations and, when giving an intramuscular injection in the thigh (particularly of cats), to avoid causing damage to the sciatic nerve. Because avian and reptilian species have a well-developed renal portal system, first-pass renal excretion may decrease the systemic availability of drugs that are primarily eliminated by the kidneys (e.g., β -lactam and aminoglycoside antibiotics) when injected intramuscularly in the thigh of birds or caudal half of the body of reptiles.

SUBCUTANEOUS INJECTION

Subcutaneous injection is an alternative route to intramuscular injection for administration of parenteral preparations to domestic animals. This route of administration is used most often in dogs and cats and only occasionally in horses. Most of the factors that influence drug absorption from skeletal muscle also apply to subcutaneous sites. They include the concentration of drug in the parenteral preparation, the nature of the vehicle and other components of the formulation, the total volume of the preparation administered, blood supply to subcutaneous tissue and area of the absorptive surface, tissue irritation, precipitation of drug at the site of injection, and persistence of drug residues. Absorption from subcutaneous sites is often slower and more erratic than from intramuscular sites because of the limited and more variable blood flow to subcutaneous tissue. However, the absorptive area may be larger and can be expanded by massaging the skin covering the region of the injection site. The degree of tissue irritation caused by some parenteral preparations appears to be greater after subcutaneous than intramuscular

Fig. 3 Mean plasma penicillin concentration–time curves after 20,000 IU of procaine penicillin g/kg was administered to 5 animals (4 horses, 1 pony) at 5 different sites. (From Ref. 29.)

injection(36, 37). Because the damaged tissue surrounding a subcutaneous injection site can be trimmed from the carcass of a slaughtered animal, the likelihood of violative drug residues in the meat is reduced. Subcutaneous injection is the preferred route of administration for some poorly soluble suspensions. When formulating sustained-release parenteral preparations, a compromise may have to be made between the rate of drug release and the degree of tissue irritation caused by the preparation. Various modified-release devices for subcutaneous implantation have been developed as an alternative to injection of sustained-release oily suspensions. Devices developed include an implantable osmotic pump that delivers growth hormone-releasing factor over a period of 7 days in steers and wethers (38). Another subdermal implant is a diffusion polymeric matrix system that releases estradiol at an approximately zero-order rate. A modified-release melatonin implant designed to advance the time of onset of cyclical ovarian activity in ewes is commercially available. Although great efforts have been made toward technological development of modified-release devices for subcutaneous implantation in cattle and sheep, the use of implants in food-producing animals does not appear to have gained wide acceptance over the past decade.

INTRAVENOUS INJECTION

When a parenteral drug solution is administered intravenously, it is assumed that the total dose of the drug is completely available systemically. This assumption overlooks the fact that an intravenously administered drug passes through the lungs, which constitute an organ of biotransformation, before being distributed throughout the body. Intravenous injection produces a prompt pharmacological response and overcomes the variability in absorption associated with other routes of drug administration. Parenterals, excluding long-acting preparations, that are too irritant to be injected by other routes may be cautiously administered intravenously. It must be ensured that perivascular leakage at the site of injection does not occur. Intravenous injection of irritant solutions can cause thrombophlebitis. Once a drug has entered the systemic circulation, its removal from the body is entirely dependent on the elimination(biotransformation and excretion) processes. Pharmacokinetic parameters that describe the disposition(distribution and elimination) of drugs are based on the plasma concentration profiles after intravenous injection of single doses. Assumptions made in the estimation of absolute bioavailability, which is based on comparison of total areas under the plasma concentration–

time curves after extravascular and intravenous administration of the drug, are that the intravenously administered dose is completely available systemically and that the clearance of the drug is not changed by the route of administration.

The vein commonly used for injecting drugs intravenously varies with the species of animal. In horses, cattle, sheep, and goats, the jugular vein is used, whereas in dogs and cats, either the cephalic (usually) or the jugular vein is used, and in pigs, an ear vein is often used. In anesthetized dogs and cats, the jugular vein is convenient to use for administering supplemental doses of intravenous anesthetics, whereas in dogs, the sublingual vein may be used in emergency situations for injecting drug solutions of small volume. In pharmacokinetic studies of drug bioavailability and disposition, blood samples are collected from the jugular vein of all species apart from pigs, in which the anterior vena cava is generally used. It is very unlikely that the vein used for collection of blood samples, with the exception of the vein used for injection of the drug, would influence the results obtained in a pharmacokinetic study involving the measurement of plasma drug concentrations over an extended period.

Because of practical considerations, intravenous infusion is used far less widely for drug administration to animals than to humans. Intravenous administration, especially constant-rate infusion, has two important advantages over other routes. It provides complete systemic availability of the drug and allows greater control over the intensity (magnitude) of the effects produced. The relatively short dosage interval associated with multiple dosing is the principal disadvantage of the use of intravenous injection in animals. Long-acting preparations administered by intramuscular injection constitute the parenteral dosage form most widely used in farm animals.

Intraosseous administration is a feasible alternative to intravenous injection of some antimicrobial agents (sodium ampicillin or amoxicillin, cefotaxime, gentamicin or amikacin sulfate) in neonatal foals (less than 7 days of age). This particularly applies in the treatment of septicemia in neonatal foals that are in a state of septic shock or dehydration or both. The plasma concentration profiles for amikacin administered intraosseously and intravenously to neonatal foals are similar (Fig. 4) (39).

PARENTERAL DOSAGE FORMS

Parenteral dosage forms for use in animals include aqueous, aqueous organic and oily solutions, emulsions,

Fig. 4 Concentrations (mean \pm S.D.) of amikacin in plasma after i.v. and i.o. administration of amikacin sulphate (7 mg/kg body weight) to 6 foals at 3 to 5 days of age.

aqueous and oily suspensions for injection, and modified-release devices for subcutaneous implantation. Parenteral preparations must be sterile and pyrogen-free; liquid formulations should, if possible, be buffered close to physiological pH and preferably be isotonic with body fluids. The advantages and disadvantages associated with the various types of parenteral dosage forms have been addressed elsewhere (40).

The formulation of an extravascularly injected parenteral preparation primarily determines the plasma concentration profile of the drug. A drug is immediately available for absorption only when administered as an aqueous solution and when neither precipitation nor tissue irritation occurs at the injection site. Gentamicin sulfate (50 mg/ml aqueous solution) is rapidly and completely absorbed in that the peak plasma concentration is attained within 30–60 min, and systemic availability exceeds 90% from intramuscular injection sites in horses, dogs, and cats. After intravenous, intramuscular, and subcutaneous injection of gentamicin (3 mg/kg) in dogs, the peak plasma concentration (10.7 μ g/ml i.m.; 10.2 μ g/ml s.c.) and absolute bioavailability (96% i.m.; 94.3% s.c.) of the antibiotic provided by the intramuscular and subcutaneous routes were similar (41). Administration of amikacin sulfate (50 mg/ml aqueous solution) by subcutaneous injection at three dose levels (5, 10, and 20 mg/kg) to dogs showed that area under the curve, which reflects the extent of absorption, was proportional to the dose administered (42). After intramuscular injection of ceftiofur sodium (as reconstituted aqueous solution) at dose levels of 1.1 and 2.2 mg of ceftiofur free acid

equivalents per kilogram of body weight to sheep, the peak plasma concentrations (C_{max}) of ceftiofur and metabolites (measured as desfuoylceftiofur acetamide by HPLC) were 4.33 and 7.13 μ g/ml, the apparent half-lives were 6.5 and 7.65 h, respectively, and the area under the curve (from time zero to the limit of quantification of the assay) was proportional to the dose administered (43). The drug was rapidly (t_{max} , 0.5–1 h) and completely absorbed from the intramuscular injection site. Ketamine hydrochloride (100 mg/ml aqueous solution) is rapidly absorbed from the intramuscular injection site in cats, but pain may be evident before onset of the anesthetic effect. In horses, dogs and cats, ketamine administration is preceded by sedative premedication with an α_2 -adrenoceptor agonist (detomidine, medetomidine, or xylazine). Parenteral solutions of an irritant nature (thiopental sodium, ticarcillin sodium-clavulanate potassium combination, cefuroxime, cefotaxime, ceftriaxone, flunixin meglumine) and digoxin injection should be administered only by the intravenous route. Formulations containing sparingly soluble drugs in a water-miscible solvent, such as propylene glycol, may cause precipitation of drug at the intramuscular injection site. This makes these preparations unsuitable for intramuscular administration (e.g., diazepam, phenytoin). Diazepam injection (5 mg/ml solution or emulsion) may be administered to dogs and cats by intravenous injection and, after appropriate dilution, by intravenous infusion.

In parenteral preparations containing a poorly soluble salt of a drug, availability of the drug for absorption, which is dependent on dissolution rather than on the absorption process per se, generally controls the rate of absorption, the peak plasma concentration, and the length of time over which effective plasma concentrations are maintained. Long-acting parenteral preparations are formulated in a nonaqueous vehicle (such as an oil), or a poorly soluble salt of the drug is used (usually an aqueous suspension). These preparations provide slow absorption of the drug over an extended period owing to its gradual or staged availability for absorption (44). Avermectins and milbemycins (macrocyclic lactones) are highly lipophilic substances that determine the extent of their distribution and deposition in body fat, whereas the formulation of parenteral dosage forms (for subcutaneous injection in cattle or sheep, but not horses) influences the plasma concentration profile after the administration of a single dose (200 μ g/kg). The commercially available preparations differ in formulation; ivermectin is a nonaqueous preparation (60% propylene glycol/40% glycerol formal), doramectin is an oil-based preparation containing sesame oil/ethyl oleate (90/10), and moxidectin is an aqueous-based solution. The pharmacokinetic parameters describing the rates of absorption and elimination of these

Table 5 Pharmacokinetic parameters describing the rate of absorption and elimination of ivermectin (IVM), doramectin (DRM), and moxidectin (MXD) after subcutaneous injection (shoulder region) of single doses (200 µg/kg) of the commercially available preparations to 10-month-old hereford calves (180–210 kg body weight)

endectocides after administration by subcutaneous injection (shoulder region) in 10-month-old Hereford calves are compared in Table 5 (45). Because the systemic availability (F) of the drugs was not determined in this study, the term clearance/systemic availability (Cl_B/F) is used. Comparison of three commercially available parenteral preparations (one conventional and two long-acting) of oxytetracycline (20 mg/kg) injected intramuscularly in the lateral neck of pigs showed statistically significant differences between the preparations in peak plasma concentration (C_{max}), time of peak concentration (t_{max}), and mean residence time (MRT), whereas area under the curve (AUC) did not significantly differ among the preparations (Table 6) (46). The results indicate that a 24-h dosage interval should be used for the conventional preparation, whereas a 48-h interval would be appropriate for either of the long-acting preparations. A single intramuscular dose (20 mg/kg) of a long-acting preparation of oxytetracycline provides plasma

concentrations above 0.5 µg/ml for 48 h in pigs, ruminant calves, cattle, goats, red deer (*Cervus elaphus*), fallow deer (*Dama dama*), and camels (*Camelus dromedarius*). The commercially available long-acting preparations of oxytetracycline should not be administered to *Equidae* (horses, ponies, and donkeys). When comparing parenteral preparations of an antimicrobial agent on the basis of potential clinical efficacy, it is generally useful to compare the areas under the inhibitory plasma concentration–time curves (AUIC = AUC/MIC₉₀) for the duration of the recommended dosage interval because this term indicates the degree of exposure of susceptible micro-organisms to the drug.

The plasma concentration profiles can vary widely among different parenteral preparations of the same drug administered by intramuscular injection, even when the same injection site is used. Comparison of the plasma concentration profiles obtained after intramuscular injection

Fig. 5 Mean plasma ampicillin concentrations after i.m. injection of 5 different parenteral ampicillin formulations at similar dose levels (7.7 ± 1.0 mg/kg) to 5 calves. (From Ref. 47.)

tion in the lateral neck of ruminant calves of five different parenteral preparations of ampicillin at a similar dose level (7.7 ± 1.0 mg/kg) serves to illustrate the variation that can exist among preparations (Fig. 5) (47). Estimation of the bioavailability of each preparation relative to a reference preparation is useful. A crossover design incorporating an appropriate washout period between the phases of the bioavailability study should be used whenever feasible.

The drug concentration in a parenteral suspension can influence the plasma concentration profile. When different concentrations of amoxicillin (100 and 200 mg/ml) in aqueous suspensions of amoxicillin trihydrate were administered intramuscularly at the same site and same dose level (10 mg/kg) to horses, the preparation of lower concentration (10%) provided relatively better absorption and a more consistent plasma concentration profile. Intramuscular injection of amoxicillin trihydrate (15% in a mixed oil base) in the neck (10 cm behind the ear) of pigs produced two peaks, 1.7 and 0.8 µg/ml at 1.3 and 6.6 h, respectively, rather than a single peak in the plasma concentration profile and an eight-fold longer mean residence time of the antibiotic than a preparation of the same concentration in oil (48). The two peaks in the plasma concentration profile could be ascribed to the mixture of oil vehicles releasing amoxicillin at different rates.

Age and body weight (45, 55, and 62, kg) of calves was shown to influence the systemic availability of amoxicillin administered intramuscularly as amoxicillin trihydrate (10% aqueous suspension). When the same preparation was administered intramuscularly to different animal species, the trend was for smaller animals (piglets, dogs, cats) to show an early high peak concentration followed by

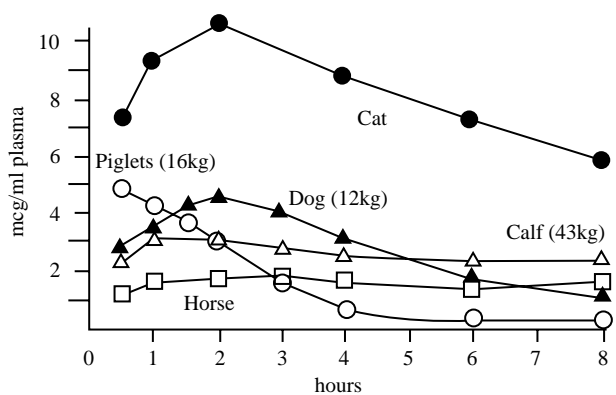

Fig. 6 Effect of species and weight on the bioavailability of amoxicillin after i.m. injection of amoxicillin trihydrate aqueous suspension (100 mg/ml) at the same dose (7 mg/kg) in the various species except cats (10–12 mg/kg).

a rapid decline, whereas larger animals (calves, horses) show a lower and relatively constant plasma concentration of amoxicillin over at least an 8-h period (Fig. 6) (49).

BOVINE MAMMARY GLAND

Antimicrobial agents, as with other drugs, cross the blood–milk barrier, which is a somewhat restrictive functional rather than anatomical barrier, primarily by passive diffusion. Both nonpolar lipid-soluble compounds and polar substances with sufficient lipid solubility passively diffuse through the predominantly lipoidal blood–milk barrier (50). At a moderate level of milk production, the ratio of the volume of blood circulating through the mammary gland to the volume of milk produced has been estimated to be 670:1; this provides ample opportunity for drugs to diffuse passively from the systemic circulation into milk. The composition (g/dL) of milk varies among breeds of cow in protein, from 3.1 (Holstein) to 3.9. (Jersey, Zebu, and buffalo) and fat, from 3.5 (Holstein) to 5.5 (Jersey, Zebu, and buffalo) content.

The milk-to-plasma equilibrium concentration ratio of total (nonionized plus ionized) drug is determined by the degree of ionization of the drug, which is pK_a/pH -dependent, in blood and milk, the charge on the ionized moiety, and the extent of binding to plasma proteins and milk macromolecules. It has been shown that only the lipid-soluble, nonionized moiety of a weak organic acid or base that is free (not bound to proteins) in the plasma can diffuse through cellular barriers and enter the milk (51). In normal lactating cows (milk pH range 6.5–6.8), weak organic acids attain milk ultrafiltrate-to-plasma

ultrafiltrate equilibrium concentration ratios less than 1; oxytetracycline and rifampin, amphoteric drugs with moderate and high lipid solubility, attain equilibrium concentration ratios of 0.75 and approximately 1, respectively; weak organic bases, apart from aminoglycosides, spectinomycin, and polymyxin B (drugs with low solubility in lipid) attain milk ultrafiltrate-to-plasma ultrafiltrate concentration ratios greater than 1 (Table 7) (52). The high concentration ratios attained by lipophilic organic bases (macrolides, lincosamides, trimethoprim) are attributed to the ion-trapping effect in acidic milk. Enrofloxacin and its active metabolite ciprofloxacin, formed by *N*-deethylation (a microsomal-mediated oxidative reaction in the liver), would be expected to attain concentrations in milk that would be effective against susceptible Gram-negative aerobic bacteria, in particular *Escherichia coli*.

In the presence of mastitis, the pH of milk increases to within the range of 6.9 to 7.2. As a consequence, the ion-

trapping effect on lipophilic organic bases is reduced, whereas the concentrations attained by weak organic acids are somewhat increased. The higher pH of milk does not change the concentrations attained by amphoteric drugs (fluoroquinolones, tetracyclines, rifampin); however, antimicrobial activity of these drugs is often lower in milk than in extracellular fluid or in vitro determination would predict.

Antimicrobial therapy is generally applied in the treatment of clinical mastitis during lactation and in treating subclinical mastitis at the end of lactation, whereas the implementation of preventive measures is essential for decreasing the incidence of mastitic infection in the dairy herd. The common causative pathogenic microorganisms of clinical mastitis are *Streptococcus uberis*, coliforms (*E. coli*, *Klebsiella* spp.), *S. aureus*, *S. dysgalactiae*, and *S. agalactiae*. It is usual to treat clinical mastitis both systemically using a parenteral antimicrobial preparation and locally with a quick-release intramammary prep-

Table 7 Comparison of calculated and experimentally obtained milk: plasma concentration ratios for antimicrobial agents under equilibrium conditions

Drug	Lipid solubility	pK _a	Milk pH	Concentration ratio (Milk ultrafiltrate: plasma ultrafiltrate)	
				Theoretical	Experimental

aration. The infusion via the teat canal of an intramammary preparation alone would be inadequate for the treatment of moderate to severe infection because of the decreased ability of an infused drug to ascend partially occluded milk ducts and the requirement, particularly in coliform mastitis, for frequent milkout (stripping) of the infected quarter of the mammary gland. In mild cases of mastitis diagnosed at an early stage of infection, the infusion of a quick-release intramammary preparation may suffice without concurrent systemic treatment. Slow-release intramammary preparations are used at the end of lactation (after the last milking) to treat subclinical mastitis and to prevent the establishment of new infections, including summer mastitis commonly caused by *Actinomyces pyogenes* during the nonlactating (dry) period. Because *S. aureus* is the principal causative microorganism of subclinical mastitis, the slow-release intramammary preparation selected for treatment should contain an antimicrobial effective against all strains of the bacterium.

PARENTERAL PREPARATIONS

An “ideal” antimicrobial agent for systemic therapy of bovine mastitis should possess the following properties (53):

1. low minimum inhibitory concentration (MIC) for the majority of mastitis-causing pathogenic microorganisms;
2. high systemic availability after intramuscular injection;
3. lipid-soluble and predominantly nonionized in the blood and have a low degree of binding to plasma proteins;
4. long apparent half-life to ensure that concentrations above (preferably severalfold) the MIC are maintained at the site of infection in the mammary gland throughout the recommended dosage interval (12 h is desirable);
5. minimal adverse effects in cows treated at effective dosage; and
6. short withdrawal periods (milk and slaughter).

Parenteral preparations with antimicrobial activity, which depends on the causative pathogenic microorganism, and pharmacokinetic properties that meet most of these criteria include procaine penicillin G (aqueous suspension), amoxicillin trihydrate–clavulanate potassium combination (aqueous suspension), and enrofloxacin (solution). Enrofloxacin is not approved for use in cows producing milk for human consumption. To attain effective concentrations in the mammary gland, oxytetracycline

hydrochloride (conventional preparation) has to be administered by slow intravenous injection. Even though macrolide antibiotics attain high concentrations in milk, they also diffuse passively into ruminal fluid (pH 5.5–6.5) where the ion-trapping effect applies. This feature of their distribution may be undesirable. Moreover, slow intravenous injection is the preferred manner of administration because the available parenteral preparations cause tissue irritation at intramuscular injection sites. Because spiramycin binds avidly to tissue components, long withdrawal periods would be associated with the use of this antimicrobial agent.

INTRAMAMMARY PREPARATIONS

Intramammary preparations are formulated to provide either quick release of the antimicrobial agent or slow release of the antimicrobial over an extended period. A requirement of all intramammary preparations is that they be reasonably nonirritating to the parenchyma (epithelial tissue) of the udder. Quick-release preparations are used primarily in lactating cows for the treatment, often in conjunction with systemic therapy, of clinical mastitis. They should have short withdrawal periods. The vehicle used and viscosity of the formulation should allow rapid release of the antimicrobial while ensuring that effective concentrations will be maintained throughout the recommended dosage interval. Access of the released antimicrobial to the site of infection is determined by its uptake and distribution in mammary tissue, which are governed by the chemical nature and physiochemical properties (in particular, lipid solubility) of the drug. Binding to milk proteins or components of mammary tissue limits distribution and extends the withdrawal periods. The transfer of an antimicrobial agent from treated to untreated quarters of the udder takes place via the bloodstream and involves passive diffusion in both directions across the blood–milk barrier. Examples of intramammary preparations formulated as suspensions and having a recommended dosage interval of 12 h include cloxacillin sodium, ampicillin sodium–cloxacillin sodium combination, trimethoprim–sulfadiazine combination, and oxytetracycline hydrochloride (oily suspension), whereas erythromycin is formulated as an intramammary solution. Cefuroxime sodium and cefoperazone sodium (third-generation cephalosporins) are formulated as an oily paste and oily suspension, respectively. Quick-release intramammary preparations have short withdrawal periods, typically slaughter, 7 days and milk-withholding, 3.5 days, or either may be shorter depending on the preparation.

Slow-release intramammary preparations may be infused at the end of lactation (after the last milking) and into the teat canal of nonlactating cows to treat subclinical mastitis and to prevent the establishment of new infections during the nonlactating period. Either a poorly soluble salt of an antimicrobial agent may be used or the formulation of the preparation be such that the rate of antimicrobial release is relatively constant, approaching zero-order. The antimicrobial must remain active (be stable) throughout the extended duration in the udder, and the preparation should not cause tissue irritation. Antimicrobial binding to mammary tissue components is not of particular concern because slow-release preparations are not used in lactating cows. However, the ability to penetrate cell membranes is important because, in chronic staphylococcal mastitis, the pathogenic bacteria often reside within epithelial cells, neutrophils, and macrophages (54). Examples of slow-release intramammary preparations include cloxacillin (benzathine salt) with aluminium monostearate (suspension), ampicillin (trihydrate) and cloxacillin (benzathine) with aluminium monostearate (suspension) or formulated without aluminium monostearate as an oily suspension, procaine penicillin G (oily paste), dihydrostreptomycin sulfate and procaine penicillin G (oily paste). Penicillins and especially aminoglycosides have limited ability to penetrate cell membranes, whereas fluroquinolones, rifampin, and macrolides have this capacity.

Compound preparations containing one or more antimicrobial agents and a corticosteroid (hydrocortisone or prednisolone) are available for intramammary infusion in lactating cows. The reduction in inflammation of the mammary gland is desirable; however, the immunosuppressant effect and decrease in phagocyte function produced by glucocorticoids are undesirable. Amoxicillin trihydrate–clavulanate potassium combination with prednisolone is an example of a compound preparation (oily suspension) that can be administered by intramammary

infusion at 12-h intervals and has short withdrawal periods (slaughter, 7 days; milk, 2 days). Unlike glucocorticoids, the nonsteroidal anti-inflammatory drugs do not cause immunosuppression. Flunixin meglumine (2.2 mg/kg) administered by intravenous injection at 24-h dosage intervals may have a place in the treatment of acute *E. coli* (endotoxin) mastitis. The significance of the antipyretic, anti-inflammatory, and analgesic effects produced by the drug is primarily dependent on the stage of the inflammatory process at which treatment is begun. Early diagnosis of coliform mastitis and prompt initiation of treatment with flunixin greatly increase the beneficial effect of the drug. The half-life of flunixin in cows is 8.1 h and the withdrawal periods are short (slaughter, 7 days; milk, 12 h). Flunixin does not interfere with the activity of concurrently administered antimicrobial agents, should antimicrobial therapy be applied. There is no evidence to support the contention that systemic antimicrobial therapy causes a massive release of endotoxin in cows with coliform mastitis. Frequent stripping of the infected quarter(s) to remove bacteria and cellular debris is important, perhaps essential, in coliform mastitis (55). The slow intravenous injection of oxytocin, 5–10 U of diluted solution (10 U/ml), facilitates the completeness of stripping (milkout).

THERAPEUTIC CONCENTRATIONS

The principal pharmacological effects produced are generally associated with the same range of therapeutic plasma concentrations in domestic animals as in humans (Table 8). The mechanisms of action of drugs appear to be the same in mammalian species. The calculation of a dosage regimen (dose and dosage interval) for a drug preparation is based on a knowledge of the therapeutic concentration range and the pharmacokinetic parameters

Table 8 Principal pharmacological effect and range of therapeutic plasma concentrations of some drugs

Drug	Pharmacological effect	Therapeutic concentrations
Quinidine	Antiarrhythmic	0–6 µg/ml
Procainamide	Antiarrhythmic	6–14 µg/ml
Lignocaine	Antiarrhythmic	1.5–5.0 µg/ml
Propranolol	Antihypertensive	20–80 ng/ml
Digoxin	Positive inotropic	0.6–2.4 ng/ml
Phenobarbitone	Anticonvulsant	10–25 µg/ml
Pethidine	Analgesic	0.4–0.7 µg/ml
Theophylline	Bronchodilator	6–16 µg/ml

that describe bioavailability and disposition of the drug. Complete systemic availability can be assumed only when a drug is administered intravenously. Species differences in the dosage regimen for a drug preparation administered by a particular route can generally, but not always, be attributed to variation among species in pharmacokinetic behavior of the drug. Species differences in susceptibility (dosage requirement) to certain drugs (morphine, xylazine) appear to be attributable to pharmacodynamic variation (affinity and/or efficacy).

Dosage of anthelmintics, which usually refers to a single dose, is based on semiquantitative assessment of clinical efficacy, although, when appropriate, bioavailability and the plasma concentration profile of the active moiety (parent drug and/or active metabolite) are considered in the development of anthelmintic dosage forms and selection of their routes of administration for various animal species (56). Because anthelmintics are administered in different dosage forms to ruminant species (cattle, sheep, and goats), pigs, horses, and small animals (dogs and cats), a wide variety of preparations are commercially available for use in animals.

DRUG DISPOSITION

Species variations in the disposition of a drug may be attributed to differences in the extent of distribution and/or the rate of elimination of the drug. Variations are usual between ruminant and monogastric species and between herbivorous and nonherbivorous species, depending on the classification system used for mammalian species. The rate of elimination of drugs differs widely between homeothermic and poikilothermic species. Little is known regarding drug distribution in poikilothermic species (fish and reptiles).

EXTENT OF DISTRIBUTION

Significant differences in the extent of distribution of drugs, particularly lipid-soluble organic bases, are usual between ruminant and monogastric species. After parenteral administration, lipophilic bases diffuse passively from the systemic circulation into ruminal fluid (pH 5.5–6.5), where they become “trapped” by ionization. These drugs are slowly reabsorbed or, if they possess functional groups suitable for metabolism by hydrolysis or reduction, they may be partially inactivated by ruminal micro-organisms.

The volume of distribution at steady state ($V_{d(ss)}$) is useful for determining the significance of changes in the extent of distribution of a drug in the presence of disease states or by plasma protein binding displacement (drug interaction) and for comparing the extent of drug distribution in neonatal and adult animals of the same species. The volume of distribution at steady state, unlike $V_{d(area)}$, is at least theoretically independent of changes in the rate of drug elimination (57).

PLASMA PROTEIN BINDING

Although the extent of plasma protein binding of a drug varies among domestic animal species, the range of binding is reasonably narrow in the collective species, and the difference among individual species is often not of clinical significance. Species variation in the binding of acidic drugs could be attributed to differences in the conformation of plasma albumin; the lower concentration of plasma albumin in birds than in mammals may generally account for the lower binding of acidic drugs in birds.

ELIMINATION PROCESSES

In domestic animal species, the liver constitutes 1.25–2.5% of live body weight, and hepatic arterial blood flow represents 26–29% of cardiac output. The hepatic portal vein contributes additionally to liver blood flow. The kidneys constitute 0.25–0.6% of live body weight and receive 22–24% of cardiac output. In avian species and reptiles, the renal portal system contributes to blood flow to the kidneys. In proportion to organ weight (mass), the kidneys are more richly perfused with blood than is the liver.

The liver metabolizes drugs, other foreign chemical compounds (xenobiotics), and certain endogenous substances (e.g., steroid hormones, bilirubin) by a variety of pathways. They include hepatic microsomal-mediated oxidative reactions, reductive and hydrolytic reactions (phase I), and conjugation (synthetic) reactions with various endogenous substances (phase II) (58, 59). Phase I metabolic reactions occur ubiquitously and are qualitatively similar in mammals, birds, and fish, but differ widely and unpredictably among species in the rates at which they take place. Although molecular structure is the primary determinant of the phase I reaction that will most likely occur, at least a moderate degree of lipid solubility is required for microsomal oxidation. The situation is

Table 9 Domestic animal species with defects in certain conjugation reactions

Species	Conjugation reaction	Major target groups	State of synthetic reaction
Cat	Glucuronide synthesis	–OH, –COOH, –NH ₂ , =NH, –SH	Present, slow rate
Dog	Acetylation	Ar–NH ₂	Absent
Pig	Sulfate conjugation	Ar–OH, Ar–NH ₂	Present, low extent

(From Ref. 50.)

different with regard to phase II metabolic reactions because some of these are either defective or absent in certain species, which makes the final pathways of metabolism somewhat predictable (Table 9) (50). Requirements of phase II reactions include the presence in a drug molecule (either parent drug or phase I metabolite) of a functional group that is suitable for undergoing conjugation, an endogenous reacting substance (conjugating agent), and a transferring enzyme. The major transferring enzymes are UDP-glucuronyltransferase, sulfotransferase, *N*-acetyltransferase, GSH-*S*-transferase, and methyltransferase. Conjugates of drugs are polar, less lipid-soluble, and consequently less widely distributed extravascularly than the parent drug or phase I metabolite, and the vast majority are pharmacologically inactive. Apart from a few exceptions (e.g., the *N*⁴-acetyl derivative of most sulfonamides), drug conjugates are more water-soluble than the parent drug. Glucuronide conjugates are especially suitable for carrier-mediated active excretion in urine or bile or both. Species variations in conjugate formation could be attributed to the availability of the conjugating agent, the ability to form the “activated” nucleolide, or the activity of the transferring enzyme (60). Fish may have a low capacity to form the activated nucleolide uridine-diphosphate–glucuronic acid, which would limit glucuronide synthesis. Prodrugs belong to a different category of drug, in that prodrugs per se are devoid of activity but are metabolically converted by phase I, usually hydrolytic reactions to the active parent drug. Examples of orally administered prodrugs include enalapril (enalaprilat), pivampicillin (ampicillin), netobimin (albendazole), and febantel (fenbendazole). Metabolic conversion (activation) of these prodrugs occurs presystemically in that it is brought about by ruminal micro-organisms or takes place during passage through the intestinal mucosa or the liver (first-pass metabolism).

Ruminal microorganisms are capable of at least partially inactivating orally administered drugs (chloramphenicol, trimethoprim, nitroxylin, digoxin) by hydrolytic and reductive reactions. The susceptibility of ruminant animals to toxicity caused by ingestion of plants containing cyanogenetic glycosides (e.g., *Prunus* spp., *Acacia* spp.,

Eucalyptus cladocalyx) is attributed to ruminal hydrolysis of the glycosides with liberation of hydrogen cyanide. Intestinal micro-organisms containing β -glucuronidase can reactivate (by hydrolysis) glucuronide conjugates of drugs excreted in bile. Renal excretion is the principal process for elimination of drugs that are predominantly ionized in the plasma, polar drugs, and drug metabolites. Extensive (>80%) binding to plasma proteins limits the availability of drugs for glomerular filtration but does not hinder carrier-mediated active tubular secretion. Although a drug may enter tubular fluid both by glomerular filtration and by proximal tubular secretion, its renal clearance may nonetheless be low when substantial reabsorption occurs in the distal nephron. Because reabsorption takes place by passive diffusion, it is influenced by the concentration of drug and its degree of ionization in distal tubular fluid and by the rate of passage of glomerular filtrate through the distal nephron. The degree of ionization is determined by the pK_a value of the drug and the urinary pH reaction. The usual urinary reaction in carnivorous species is acidic (pH 5.5–7.0), whereas in herbivorous species it is alkaline (pH 7.2–8.4). The excretion of weak organic acids is enhanced under alkaline and decreased under acidic urinary conditions; the converse applies to weak organic bases. Species variations in the rate of elimination of renally excreted drugs (penicillins, most cephalosporins, aminoglycosides, most diuretics, nondepolarizing neuromuscular blocking drugs) are primarily attributable to differences in the glomerular filtration rate (GFR). Based on inulin clearance, mean values of GFR (ml/min \times kg) are 3.96 in dogs; 2.94 in cats; 2.80 in pigs; 2.26, 2.25, and 2.20 in goats, cattle, and sheep, respectively; and 1.65 in horses; the estimated value of GFR in humans is 1.84 ml/min \times kg. Urinary pH influences the rate of elimination of drugs that are moderately lipid-soluble and undergo elimination both by hepatic metabolism and by renal excretion (amphetamine, trimethoprim, phenobarbital, sulfonamides).

The rate of hepatocyte secretion of bile in domestic animal species is 12–24 ml/kg per day; the lower end of the range applies to the dog and cat, and the upper end applies to the horse (a species that does not have a gall bladder). Compounds excreted in bile have molecular weights

exceeding 300 and a degree of polarity that enables them to be transported by a carrier-mediated process from hepatic parenchymal cells into bile. Drugs and drug metabolites (primarily conjugates) excreted in bile enter the duodenum, from which some (depending on their lipid solubility) may be reabsorbed by passive diffusion.

RATE OF ELIMINATION

Half-life is the pharmacokinetic parameter used to measure the overall rate of drug elimination. The half-life of most drugs that are primarily eliminated by hepatic biotransformation varies widely among species (Table 10). The usual trend is that half-life is shorter in cattle and horses (herbivorous species) than in dogs and cats (carnivorous species), whereas the half-life of several drugs is longer in humans than in domestic animals. There are, however, notable exceptions to this trend, such as the methylxanthines (caffeine and theophylline) in horses and phenylbutazone in cattle. The half-life of phenylbutazone in cattle varies from 42 to 66 h and, unlike in horses, dogs, and humans, does not appear to be dose-dependent. Because of differences in the rate of hepatic elimination (presumably by biotransformation), the half-life of various drugs (sulfamethazine, trimethoprim, ceftiofur/desfuroylceftiofur, closantel, clorsulon) is shorter in goats (especially dwarf goats) than in sheep, whereas the half-life of some drugs (phenylbutazone, norfloxacin) is shorter in donkeys than in horses and ponies.

Because phenytoin, valproate, carbamazepine and clonazepam have a much shorter half-life in dogs than in humans (Table 11), the dosage intervals that would be required for anticonvulsant effectiveness in dogs make conventional dosage forms of these drugs impractical for therapeutic use (61). The half-life of phenobarbital and naproxen is 2-fold longer in mongrel (mixed-breed) dogs than in Beagles. The long half-life of naproxen in dogs (74 h in mongrels, 35 h in Beagles) is unusual for a nonsteroidal anti-inflammatory drug. Naproxen half-life is 13.9 h in humans, 8.3 h in horses, 4.8 h in minipigs, and 1.9 h in Rhesus monkeys.

The half-life of salicylate, which is primarily eliminated by glucuronide conjugation, is 25–35 h and dose-dependent in cats, compared with 10–15 h in humans, 8.6 h in dogs, 1 h in horses, and 0.8 h in cattle. A relative deficiency of hepatic microsomal glucuronyl-transferase activity appears to be characteristic of *Felidae*, because it applies not only to the domestic cat (*Felis catus*) but also to the lion (*Panthera leo*), African civet (*Viverra civetta*), and forest genet (*Genetta pardina*) (62). Even though dogs and foxes (*Canidae*) are unable to acetylate aromatic (ArNH_2) and hyrazine (RNHNH_2 or ArNHNH_2) amino groups, the absence of this metabolic pathway does not appear to delay the elimination of drugs with these functional groups (sulfonamides, procainamide). Either a larger fraction of the systemically available dose is excreted as parent drug in the urine or an alternative metabolic pathway compensates for the absence of acetylation of these amino groups. Amino acid conju-

Table 10 Species variations in the half-life of some drugs that are primarily eliminated by hepatic metabolism

Drug	Cattle	Horse	Dog	Human

^aHalf-life is dose-dependent.^bParent drug and active metabolites.

gation in domestic animal species often involves glycine as the endogenous reacting substance. Glycine conjugation takes place in both the liver and the kidneys of domestic animals other than the dog, in which it occurs only in the kidneys. The transferring enzyme, which is located in mitochondria, is acyl-CoA glycinetransferase. Glycine is replaced by ornithine as the conjugating agent in birds classified as anseriformes (ducks, geese) and galliformes (chickens, turkeys) but not in columbiformes (pigeons, doves) (59).

Even though exceptions exist, which is inevitable in view of the variety of metabolic pathways, the half-life of the majority of drugs that undergo extensive hepatic biotransformation is shorter in laboratory animal species (mice, rats, guinea pigs, rabbits) and Rhesus monkeys than in domestic animal species and humans. Consistent with this trend is that the average half-life of antipyrine, a marker substance used to indicate hepatic microsomal oxidative activity, is shorter in laboratory animals (0.2–1.4 h) and Rhesus monkeys (1.2 h) than in domestic animals (1.75–3.25 h) and especially humans (10.3–12.7 h). It has been hypothesized (63) that the lesser capacity of humans to metabolize drugs by hepatic microsomal oxidation may be correlated with their enhanced longevity, expressed as maximum lifespan potential. Based on an equation using brain weight and body weight, maximum lifespan potential is estimated to be 93 y in humans, 39 y in horses, 20 y in dogs, 14 y in cats and, for comparative purposes, 77 y in African elephants.

As with the situation in mammals, wide variations exist among avian species in the half-life of drugs that are primarily eliminated by hepatic biotransformation (64). The half-life of antimicrobial agents is prolonged in poikilothermic species (fish and reptiles), which is consistent with their much lower metabolic turnover rate (65), and is influenced by ambient (in the case of fish, water) temperature (Table 12). The rate of drug elimination

increases (i.e., half-life decreases) with increase in ambient temperature and varies among fish species.

Species variations in the half-life of drugs that are eliminated by renal excretion is less pronounced than for lipid-soluble drugs that undergo extensive hepatic biotransformation. The half-life of gentamicin, which is eliminated solely by glomerular filtration, is 0.5–1 h in laboratory animals, 1.25–2.5 h in domestic animals, 2.75 h in humans, 1.25–3.4 h in various avian species, and 12 h in channel catfish (*Ictalurus punctatus*) acclimatized at 22°C. In mammalian species, the half-life of gentamicin reflects the relative (not actual) rate of glomerular filtration and is unrelated to urinary pH reaction. The volume of distribution of gentamicin is similar (250–300 ml/kg) in the various species.

The half-life of drugs that undergo a high degree of enterohepatic circulation may vary widely among species and may be relatively more prolonged in fish. The half-life of oxytetracycline is 80.3 h in African catfish (*Clarias gariepinus*) acclimatized at 25°C and 89.5 h in rainbow trout (*Salmo gairdneri*) at 12°C (66) compared with half-life of 9 h in humans, 3.4–9.6 h in domestic animals, and 1.3 h in rabbits. A combination of variables, which include the extent of distribution and the degree of enterohepatic circulation, contributes to species variation in the half-life of digoxin, which ranges from 7.8 h in cattle to 35 h in cats.

CLEARANCE

The systemic clearance of propofol, based on measurement of blood concentrations, in humans (31 ml/min × kg) and dogs (59 ml/min × kg) exceeds liver blood flow, which is 24 and 42 ml/min per kilogram of body weight in humans and dogs, respectively. It can be concluded that another organ (the lungs) or extrahepatic tissue contrib-

Table 12 Half-life of some antimicrobial agents in various species of fish

Antimicrobial agent	Fish species	Acclimatization temperature (°C)	Half-life (h)

utes to the elimination (metabolism) of propofol. The blood propofol concentration at which dogs return to the sternal position and human beings regain consciousness appears to be the same (1 µg/ml).

When applied to conventional (immediate-release) aminophylline tablets, the dosing rates that would provide an average steady-state plasma theophylline concentration of 10 µg/ml and produce a sustained bronchodilator effect are 10 mg/kg administered at 8-h dosage intervals to dogs and 5 mg/kg administered at 12-h intervals to horses or cats. The systemic clearance of theophylline is 2.5 times higher in dogs (100 ml/h × kg) than in horses and cats (40 ml/h × kg), whereas systemic availability of the drug from the oral dosage form is similar (90–100%).

INTERSPECIES SCALING

The basic assumption in interspecies scaling is that physiological variables and biochemical processes are related to the body weight of mammalian species. The use of clearance, a physiologically based parameter, may be more appropriate than half-life (a hybrid parameter) for

interspecies allometric scaling of drug elimination. A double logarithmic plot of the pharmacokinetic parameter of interest versus body weight of the animal species is used to verify the linearity of the allometric relationship.

The systemic clearance of structurally unrelated drugs that undergo elimination by various processes shows a high degree of correlation with the body weight of several animal species (Table 13). Inulin (marker substance) and gentamicin are eliminated by glomerular filtration and ampicillin by glomerular filtration and proximal tubular secretion, whereas oxytetracycline undergoes enterohepatic circulation and consequently is slowly excreted by glomerular filtration. Enrofloxacin, theophylline, and antipyrine are poorly extracted by the liver, which implies that their clearance may be influenced both by the unbound fraction in blood and by the metabolic capacity of the liver and are eliminated by phase I hepatic metabolism. Enrofloxacin and theophylline are eliminated primarily by microsomal-mediated oxidative reactions, whereas antipyrine (marker substance) is eliminated entirely by microsomal oxidation. Interspecies scaling of antipyrine clearance identifies the human as a nonconforming species, which is attributed to the substantially lower microsomal oxidative capacity of humans relative to the 10 other species studied. Because of species variations in

Table 13 Allometric relationship between the clearance (ml/min) of some drugs and body weight (kg) of various mammalian species

Drug	Elimination process	No. of species	Allometric		Correlation coefficient
			Coefficient	Exponent

binding to plasma proteins, the use of hepatic intrinsic clearance of unbound drug, rather than systemic clearance, would represent a refinement of the allometric scaling technique. This refinement has been applied to interspecies scaling of antipyrine (67) and theophylline (68). Additional correction could be made for maximum lifespan potential (63). Because the clearance of highly extracted drugs that undergo extensive phase I hepatic metabolism is primarily determined by a single physiological variable (liver blood flow), interspecies allometric scaling should be feasible for drugs in this category. The index of drug elimination (half-life, systemic clearance, organ clearance of unbound drug) to use depends on the level of refinement required.

With regard to organ (liver, kidney, heart) weights, physiological variables (liver blood flow, renal function, cardiac output, basal oxygen consumption), and the pharmacokinetic parameters systemic clearance and volume of distribution, the numerical value of the allometric exponent is generally in the range of 0.67 to 1. For physiological periods (heartbeat time, duration of respiratory cycle), turnover times (serum albumin, total body water, blood circulation), and drug half-life, the allometric exponent is often close to 0.25, which represents that for energy expenditure in mammalian species (69) and the turnover time of endogenous processes (63).

The reliability of predictions based on interspecies allometric scaling of drug disposition depends on the use of a sensitive and precise analytical method for quantification of the drug (and active metabolite) in blood or plasma, a knowledge of the principal elimination

process for the drug, the use of at least four animal species representing a wide range of body weight (based on log body weight ratio), and the identification, for possible exclusion, of any nonconforming species. Because of the uniqueness of each animal species, application of the technique for predictive purposes should be limited to the preclinical stage of drug development.

IMPLICATIONS OF STEREOISOMERISM

Stereoisomerism has implications in the formulating of dosage forms and because a chiral environment exists within the body, in determining both the degree of activity and the disposition of racemates. The enantioselective behavior of drugs used in domestic animals was comprehensively reviewed by Landoni et al. (70).

Because stereoselective processes are species-related, the enantiomeric ratios of plasma concentrations at various times and areas under the plasma concentration-time curves may differ among animal species after the administration of a drug racemate. Chiral inversion, which occurs to a variable extent in different species, can be equivocally established only by administering individual enantiomers to the animal species of interest and measuring, using a sensitive stereospecific analytical method, the enantiomer administered and the optical antipode in biological fluids and tissues. The pharmacokinetic parameters based on plasma concentration-time data for each of the enantiomers can be statistically compared.

The 2-arylpropionic acid ("profen") nonsteroidal anti-inflammatory drugs, each of which contains a single chiral center, are formulated as racemic (50:50) mixtures of the S(+)- and R(-)- enantiomers, with the exception of naproxen, which is formulated as the S(+)-enantiomer. Based on inhibition of cyclo-oxygenase activity, the S(+)-enantiomer is the eutomer (more potent enantiomer). These drugs differ markedly in both pharmacodynamic activity and pharmacokinetic behavior and, in addition, enantiomer pharmacokinetics of each drug varies among animal species. After intravenous administration of racemic ketoprofen to horses, sheep, and 20-week-old calves and measurement of individual enantiomers in plasma, significant differences between the enantiomers were found in systemic clearance in horses and in both systemic clearance and volume of distribution in sheep (Table 14), whereas values of the pharmacokinetic parameters in calves did not differ between the enantiomers (71–73). The S(+)- to R(-) ratio of area under the curve was 1.35:1 in horses, 0.54:1 in sheep, and 1.05:1 in calves. The predominant enantiomer in plasma was S(+) in horses, R(-) in sheep, and both enantiomers were present in equal concentrations in calves. After the administration of each enantiomer separately to these species, the extent of chiral inversion from the R(-)- to S(+)-enantiomer was estimated to be 49% in horses, 5.9% in sheep, and 31% in calves (72, 74, 75). Unidirectional chiral inversion was estimated to be 49% in *Cynomolgus* monkeys (*Macaca*) (76), 9% in humans (77), and varied from 27 to 66% in laboratory animal species (78). The oral bioavailability of the S(+)-enantiomer of ketoprofen in Beagle dogs is not affected by the proportion of the R(-)-enantiomer in the oral dosage form, even though considerable (73%) metabolic inversion from the R(-) to the S(+)-enantiomer occurs in dogs (79).

It is usual in humans for the S(+)-enantiomer of 2-arylpropionic acids to predominate in plasma and for the S(+)- to R(-)-enantiomeric ratio of plasma concentrations to increase with time after administration of the racemate, which is often attributed to metabolic inversion of the chiral center of the R(-)-enantiomers to their S(+)-antipodes (80). In humans, the S(+)-enantiomer is generally eliminated more slowly than is the R(-)-enantiomer. The extent of chiral inversion of fenoprofen, which has been attributed to the differential rate of formation of the CoA-thioester by hepatic microsomes (81, 82), varies widely among species. It has been estimated to be 90% in dogs (83), 80% in sheep (81), 73% in rabbits (84), 60% in humans (85), 42% in rats (86), and 38% in horses (83).

Carprofen, a weak inhibitor of cyclo-oxygenase but which produces a significant antioedematous effect in dogs (87) and horses (88) and has potent antiplatelet-aggregating properties, does not appear to undergo chiral inversion in either direction in horses, calves, dogs, cats, and humans. After intravenous or oral administration of racemic carprofen, which contains a 50:50 mixture of the enantiomers, to horses (i.v.), 8- to 10-week-old calves (i.v.), cats (i.v.), and dogs (p.o.), the R(-)-enantiomer predominated in the plasma and the R(-)- to S(+)-enantiomeric ratio of plasma concentrations increased with time after administration of the racemate. The increasing R(-):S(+) enantiomeric ratio of plasma concentrations with time can be attributed to stereoselective hepatic metabolism, although stereoselective binding to plasma albumin could contribute. A contrasting situation to that which occurs in domestic animals was found in rats and humans, in that the S(+)-enantiomer predominated in plasma and the R(-):S(+) enantiomeric ratio of plasma concentrations decreased (although only slightly in humans) with time after administration of the racemate (89, 90). The R(-)- to S(+) ratio of area under

(From Refs. 71 and 72)

the plasma concentration–time curve (AUC) was 4.5:1 in horses (91), 2.0:1 in cats (92), 1.8:1 in dogs (87), and 1.4:1 in calves (93), after administration of the racemate. Area under the curve enantiomeric ratios in rats and humans were not determined.

Ketamine, which is present in the commercially available preparation as a 50:50 mixture of the S(+)- and R(–)-enantiomers, is metabolized by hepatic microsomal *N*-demethylation to the corresponding norketamine (metabolite I) enantiomers. Based on the reported eudismic ratio of S(+):R(–) for ketamine enantiomers of 2.9:1 and the observed duration of unconsciousness in dogs and the plasma concentrations in humans at time of emergence from anesthesia which are 0.5 [S(+)] and 1.7 [R(–)] $\mu\text{g/ml}$, it can be concluded that the S(+)-enantiomer is three times more active than is the R(–)-enantiomer (94, 95). After intravenous injection of racemic ketamine, the S(+)-enantiomer of norketamine predominated in the plasma of horses (96) and dogs (97). This could be attributed to enantioselective *N*-demethylation. Systemic clearances of racemic ketamine are 15, 28, and 29 ml/min \times kg in humans, horses, and dogs, respectively. Because the disposition of the individual enantiomers administered separately has not been studied, comment cannot be made regarding the extent of chiral inversion.

Whether a racemate or an enantiomer of a chiral drug should be used in formulating dosage forms depends on the relative pharmacodynamic activity and the potential toxicity (or side effects) of the individual enantiomers, their pharmacokinetic profiles, and, importantly, the proportions formed over time in the target animal species. Binding to plasma and tissue proteins, hepatic microsomal oxidative reactions, and probably glucuronide conjugation and carrier-mediated excretion processes are stereoselective and vary among animal species. First-pass metabolism may influence oral bioavailability of the enantiomers of chiral drugs that are highly extracted by the liver and administered as racemic mixtures. When both enantiomers of a drug with a single chiral center show distinct and desirable effects (e.g., most opioids, dobutamine, bupivacaine), even though they differ in pharmacodynamic activity or when their action and the effects produced are not stereoselective, the formulating of racemic mixtures may be entirely justifiable (98). Nonetheless, because of species variation, pharmacokinetic profiles of the individual enantiomers should be determined using stereospecific analytical methods (99–102) to calculate optimum dosage for the various animal species. Use of the more active enantiomer (eutomer) in formulating dosage forms should be considered when the enantiomers differ widely in pharmacodynamic activity [e.g., S(–)-propranolol, the S(+)-enantiomer of the 2-arylpropionic acid nonsteroidal

anti-inflammatory drugs, *d*-propoxyphene] or toxic potential (levamisole is the *l*-isomer of racemic tetramisole, which can produce many side effects). To selectively produce a certain effect, a distomer (less potent enantiomer) could be formulated as a particular dosage form, e.g., R(+)-timolol as eyedrops to reduce intraocular pressure (glaucoma), R(+)-verapamil as a parenteral or oral dosage form for the treatment of angina (103). The use of an enantiomer, a single chemical entity, would increase selectivity of action, reduce total exposure to the racemate, and simplify dose–response relationships. When an enantiomer is used in formulating dosage forms, it must be optically pure. Bioequivalence assessment of a generic drug preparation requires that the generic preparation contain the racemic drug or the enantiomer corresponding to whichever is present in the innovator (reference) dosage form.

PERCUTANEOUS ABSORPTION

The skin accounts for approximately 10% of live body weight in cattle, goats, and dogs; 7.5% in horses; and 3.7% in humans. Although skin receives approximately 6% of cardiac output, cutaneous blood flow rate to various regions differs among species (104). In humans and pigs, the cutaneous circulation supplies blood (in musculocutaneous arteries) to both the skin and the underlying musculature, whereas in dogs and cats (loose-skin species), blood is supplied directly to the skin.

ABSORPTION PROCESS

The absorption process for a topically applied drug essentially involves the following stages: dissolution of the drug in and release from the vehicle, drug penetration (by diffusion) through the *stratum*, and permeation through the “living” layers of the epidermis to the underlying dermis where absorption into the systemic circulation takes place. Although the initial stage is formulation-dependent in that it relates to the form of the drug and the nature of the vehicle, the translocation stages are primarily governed by the molecular structure and physicochemical properties of the drug. Penetration of the stratum corneum is generally the rate-limiting step in the absorption process (105). Only lipid-soluble drugs can diffuse through the dead, compacted, keratinized cells (corneocytes) of the stratum corneum. However, passive diffusion through the epidermis, including the stratum corneum, can take place by one, or more, of the following routes:

transcellular through the corneocytes, intercellular through the lipid matrix (a tortuous path), or along the sweat gland ducts and hair follicles (appendageal path). Even though lipophilic substances may penetrate the stratum corneum by transcellular diffusion, some degree of water solubility is required for passage through the "living" layers of the epidermis. Polar drugs have a low capacity to penetrate the stratum corneum but may gain access to the "living" epidermal layers by shunt diffusion along the appendageal path. Additional factors that influence percutaneous absorption include the nature of the vehicle, the state of hydration of the stratum corneum, drug persistence in the stratum corneum or other strata of the epidermis, biotransformation in the epidermis, and species differences in histological structure of skin. In aquatic mammals, the stratum corneum is very thick, and the corneocytes are solidly apposed, whereas the epidermis is devoid of a stratum granulosum regardless of whether the skin is glabrous (as in whales) or hairy (as in seals) (106).

The average thickness of the stratum corneum in laboratory and domestic animals and humans is in the range of 10 to 35 μm . The thickness of this epidermal layer might not influence the penetration of chemical substances, whereas the density of appendages per unit surface area, which differs among animal species, does influence passage through the epidermis. Human skin contains an average of 40–70 hair follicles and 200–250 sweat glands per square centimeter, whereas cattle skin contains approximately 2000 hair follicles, with associated sweat and sebaceous glands, per square centimeter (107). The mean follicle density in 10 British breeds of sheep varies from 1000 to 2000 per square centimeter of skin, with a secondary-to-primary follicle ratio of 2.4:1–5.9:1 (108). The ratio of secondary to primary follicles appears to be higher in Merino sheep skin in wool-growing regions. The sebaceous glands of cattle and sheep exude large quantities of lipid material (lanolin in the case of sheep) that serve to protect their skin. The emulsifying properties of exocrine secretions may enhance dissolution and thus facilitate percutaneous absorption of topically applied compounds in cattle and sheep. Seasonal changes in the composition of secretions may cause variations in absorption of moderately lipid-soluble drugs (e.g., levamisole applied by "pour on") at different times of the year (109). Because of the larger number of skin appendages per unit of surface area, the appendageal path will likely contribute more to percutaneous absorption of hydrophilic substances in cattle and sheep than in other species. Horses and humans have highly effective sweat glands, whereas cattle, sheep, pigs, dogs, and cats are unable to sweat profusely. Changes in ambient temperature appear to affect animal skin temperature to a higher degree than human skin

temperature, which suggests that skin plays a greater role in thermoregulation in humans than in animals.

The state of hydration of the stratum corneum, which is normally maintained at 10–15%, affects the rate of penetration of chemical substances. By increasing the state of hydration to 50%, the rate of permeation of some chemical substances through the epidermis can be increased up to 10-fold (110). Occlusion has been shown to enhance the pharmacological effect of topically applied hydrocortisone and fluocinolone acetonide (111); however, percutaneous absorption of drugs is not necessarily increased. The degree of occlusion-induced absorption enhancement appears to increase with increasing lipophilicity of drug substances.

Formulations containing an absorption-promoting substance, such as propylene glycol or sodium lauryl sulfate, may increase the permeability of the stratum corneum to water-soluble drugs. Propylene glycol is a commonly used vehicle in topical corticosteroid preparations for veterinary use. Various aprotic solvents, which include dimethylacetamide, dimethylformamide, dimethylsulfoxide, tetrahydrofurfuryl alcohol, and 2-pyrrolidone, serve as penetration enhancers of polar drugs (112). Dimethylsulfoxide (DMSO) is used in formulating some topical veterinary preparations. The penetration-enhancing property of DMSO is markedly concentration-dependent. At concentrations below 50% DMSO is water, the penetration rate of many drugs differs little than from aqueous solutions. The penetration rate of levamisole through skin of cattle and sheep was somewhat slower from a formulation containing DMSO (concentration not specified) than from an aqueous solution of the drug (107). Plasma and gastrointestinal fluid concentrations of levamisole were lower after pour-on application to cattle than after oral administration or subcutaneous injection of the drug (109). Parathion penetrated the skin of pigs more rapidly when formulated in DMSO than in other vehicles (glycerol–formal/isopropanol mixture, octanol, macrogol 400) (Table 15) (113). The formation of a stable 2:1 water hydrate at a concentration of 67% v/v DMSO may explain its dehydrating and penetration-enhancing effects when present at high concentration (114). These effects are accompanied by, or perhaps attributable to, epidermal tissue damage. Mineral oil may be used in formulating long-acting, water-based topical preparations of synthetic pyrethroids (permethrin, cypermethrin) for application to ruminant animals. This type of preparation would not be washed off by rain and could provide protection against flies for an extended period. Water-insoluble substances can be formulated as emulsifiable concentrates. The emulsifiable concentrate contains one or more surfactants and produces an emulsion or micellar solution with the

water-insoluble drug in the nonaqueous phase when mixed with water (107).

SPECIES VARIATIONS

The barrier properties of skin vary with the species of animal and within a species may differ between regions of the body. Based on limited data obtained from in vitro studies of skin permeability, it could be speculated that species can, in general, be ranked in the following order: rabbits > rats > guinea pigs > cats > dogs > pigs and Rhesus monkeys > humans (least permeable skin). Because of a lack of data, horses, cattle, sheep, and goats are not included in the comparison of skin permeability. The emulsifying property and occlusive effect of sebum and the high density of appendages per unit of surface area would be expected to facilitate percutaneous absorption of substances in ruminant species.

The maximal rate of penetration of an organophosphorus compound through skin sections excised from the dorsal thorax of various species generally supports the skin permeability ranking of species vide supra (Table 16) (115). The compound rapidly penetrated the skin of rabbits and rats, whereas penetration through pig skin occurred more slowly than through skin of the other species. Even though pig skin and human skin are similar in many respects (116), percutaneous absorption of a variety of compounds in the pig was found to range from zero to four times that in humans in vivo (117). Advantage can be taken of the often similar permeability characteristics of pig and human skins with avoidance of the systemic/fat distribution difference in vivo by using the isolated perfused porcine skin flap in vitro model (118, 119). The diffusion of chemical substances through skin and

metabolism within the skin can be determined by assay of the perfusate. The sum of the amount of compound that diffused into the perfusate and the residual amount in the skin preparation at the end of the exposure period to the drug provide an estimation of percutaneous absorption.

Regional variations in percutaneous absorption contribute to differences in the systemic availability of a drug depending on the site of topical application. The Rhesus monkey (*Macaca mulatta*) could probably serve as an animal model for human skin regional variation (120).

The absolute bioavailability of a topically applied drug can be determined only by measurement of plasma concentrations and comparing total areas under the curves or, less reliably, the amounts excreted in urine over a period of at least six half-lives after topical application and intravenous injection of the drug. An appropriate washout period must be allowed to elapse between the phases of a crossover study, which is the experimental design that should be used whenever feasible. Because of species

variations in ultrastructure of skin, cutaneous blood supply, density of appendages per unit of surface area, and activity of biotransformation pathways, the percutaneous absorption (rate and extent) of a drug is best determined by performing the study in the species of interest.

CUTANEOUS BIOTRANSFORMATION

Epidermal cytochrome P450 and hydrolytic enzymes in the lipid matrix of the stratum corneum as well as in the stratum granulosum may be involved in conversion reactions of topically applied steroids (121). In pigs, epidermal cytochrome P450 has been shown to convert parathion to paraoxon by oxidative desulfuration (122). The oxygen analog formed is rapidly hydrolyzed to inactive metabolites. The significant difference between mammals and insects in the rate at which the hydrolytic reaction takes place accounts for the selective toxicity of thiophosphate insecticides. The extent to which the ultrastructural difference in the epidermis of aquatic and terrestrial mammals affects the activity of drug-metabolizing enzymes in skin is not known. Fish appear to be unable to detoxify thiophosphate insecticides.

Benzoyl peroxide, the active ingredient in some shampoos for dogs, is almost completely metabolized to benzoic acid in the epidermis. Benzoic acid undergoes conjugation with glycine, primarily in the liver, and is excreted in urine as hippuric acid. Methylation of norepinephrine to epinephrine, an *N*-transferase-mediated conjugation reaction, in human and animal skin preparations has been reported (123).

Biotransformation of propranolol, which involves microsomal-mediated oxidative reactions and glucuronide conjugation, is stereoselective in both the liver and the skin. Based on in vitro studies, using intact human skin and microsomal preparations, of percutaneous absorption and metabolism of racemic propranolol, it was concluded that the *S*(-)-enantiomer (eutomer) is metabolized more efficiently by skin than is the *R*(+)-enantiomer (124). The converse applies to hepatocytes, which metabolize the *R*(+)-enantiomer more efficiently (125). The cytochrome P450 mono-oxygenase enzymes in skin, as in the liver, can be induced (by dexamethasone, for example) or inhibited (chloramphenicol, imidazole antifungal agents). The clinical significance of altered microsomal enzyme activity in the epidermis has not been established. Metronidazole, which is available as a topical gel, inhibits acetaldehyde dehydrogenase (a nonmicrosomal enzyme); however, whether the enzyme is present in skin does not appear to be known.

TOPICAL PREPARATIONS

There is a wide variety of veterinary drug preparations available for topical application to the skin. Although most of these preparations are intended to produce local effects, some are formulated to distribute via the systemic circulation to skin covering all regions of the body or to produce systemic effects. Because of the prevalence of ectoparasites, several ectoparasiticide preparations are available for topical application by various methods depending on the animal species (Table 17). Liquid concentrates, which must be appropriately diluted before use, and prepared solutions are convenient to apply and, depending on susceptibility of the ectoparasite and persistence of the drug in skin, may provide effective treatment and protection against reinfestation for an extended period. The usual method of application of prepared solutions is by pour on to cattle, sheep, pigs, and horses, whereas "spot on" is preferred for dogs and cats. The active ingredient in preparations for pour-on application must be sufficiently lipid-soluble for percutaneous absorption to occur, and the preparation should provide residual activity in the stratum corneum and stratum germinativum and not be removed from the skin by environmental conditions (such as rain) or by rubbing. Diluted liquid concentrates are applied by spray to cattle, horses, pigs, and poultry and by either dip or spray to sheep. Because of the large quantity of drug required for dipping sheep and the difficulty of safe disposal of dip, application of diluted liquid (dip) concentrate as a spray, but at a higher

Table 17 Dosage forms and methods of application of topical ectoparasiticide preparations to individual species

Synthetic pyrethroids: cypermethrin, deltamethrin, fenvalerate, flumethrin, permethrin.

concentration than that used in the dip bath, is becoming a popular method of ectoparasiticide application by sheep farmers. The relative effectiveness of spraying versus dipping sheep for the treatment and prevention of ectoparasite infestation is open to question. When choosing between an organophosphorus compound (dimpylate, propetamphos) and a synthetic pyrethroid (flumethrin, cypermethrin) for dipping sheep, a consideration (in addition to residual protection) that could be of practical relevance is that there is no withdrawal period associated with the use of synthetic pyrethroids. The low toxicity of pyrethroids in mammals is primarily attributed to the rapid biotransformation by ester hydrolysis and/or hydroxylation (phase I metabolic reactions). Unlike mammals, fish are extremely sensitive to pyrethroid toxicity.

Synthetic pyrethroids (cypermethrin, deltamethrin, fenvalerate, flumethrin, permethrin) are available in a variety of dosage forms for topical application to domestic animals (Table 18). The appropriate dosage form of a

pyrethroid is primarily determined by the animal species, whereas due consideration is given to the ectoparasites and insects that affect the species. Aerosol sprays are more suitable for application to dogs than to cats, because cats resent (fearful response) being sprayed and lick the applied preparation from their coat. The combination preparation containing fenvalerate (0.09%), a synthetic pyrethroid, and diethyltoluamide (9.5%), a cutaneous penetration-enhancing substance, has been reported to cause acute toxicity in cats and occasionally in dogs (126, 127).

Macrolide endectocides (ivermectins and milbemycins) have activity at low concentrations against both internal (nematode) and external (arthropod) parasites. Veterinary preparations of ivermectins include parenteral solutions (for subcutaneous injection), various oral dosage forms, and topical solutions (Table 19). The different preparations are specifically designed for use in certain animal species. The topical solution of ivermectin or doramectin is applied to cattle by pouron, whereas the

Table 19 Dosage forms and routes of administration of avermectins to various animal species

Dosage form	Avermectin	Animal species	Route of administration
Parenteral			
Solution	Ivermectin, doramectin	Cattle, sheep	S.C. injection
	Ivermectin	pigs, (cats)	S.C. injection
Oral			
Solution	Ivermectin	Sheep, goats	Drench

Controlled-release ruminal capsule	Ivermectin	Sheep	P.O.
Premix	Ivermectin	Pigs	Addition to feed
Paste	Ivermectin	Horses	P.O.
Tablet	Ivermectin	Dogs	P.O.
Topical			
Solution	Ivermectin, doramectin	Cattle	Pour on
Solution	Selamectin	Dogs, cats	Spot on

topical solution of selamectin is applied to dogs and cats by spot-on. Preparations for spot-on application contain concentrated solutions of ectoparasiticides and should be applied directly to the skin at one (cats) or two (dogs) locations where the animal is unable to ingest the drug by licking. The back of the neck is one such site. The total dose of drug to apply will vary with the animal species (lower dose for cats) and with the range of body weight (dogs). Selamectin solution, for example, is commercially available in six dose sizes (from 15 to 240 mg).

The classes of ectoparasiticide and the dosage forms used in cattle, an arbitrarily selected species, are shown in Table 20. Even though different classes of drug may have activity against a similar range of ectoparasites, the drugs that belong to the various classes differ in clinical effectiveness. Quantitative differences in clinical effectiveness could be attributed to parasite susceptibility, which would be decreased by the development of resistance, and to the combined effect of drug access to the site where the parasite is located and persistence of the drug in skin. Both access and persistence are influenced by the physicochemical properties of the drug, the formulation of the preparation, and the method of application to the animal.

Dermatological preparations containing antibacterial agents include aerosol sprays (oxytetracycline hydrochloride, neomycin sulfate in propylene glycol), gels

(metronidazole, fusidic acid), creams (gentamicin sulfate, neomycin sulfate and zinc bacitracin, silver sulfadiazine), ointments (chlortetracycline hydrochloride, sodium fusidate, framycetin sulfate and gramicidin, neomycin sulfate, zinc bacitracin, polymyxin B sulfate), and dusting powders (chlortetracycline hydrochloride and benzocaine). The type of preparation influences the stability and release of the active ingredients. Gels and creams are generally easier to apply to animals but are less occlusive than ointments. Ointments provide a longer duration of drug action, and the occlusive effect may enhance preparation of the active ingredient(s) to the site of infection.

The selection of an antibacterial agent should be based on the clinical diagnosis and, whenever feasible, in vitro culture and susceptibility testing (when considered necessary) of the micro-organisms(s) isolated. In the treatment of superficial skin infections, a topically applied antibacterial preparation may suffice. However in severe and deep-seated skin infections, both local and systemic therapy should be applied. The avoidance of antagonism requires that due consideration be given to the mechanisms of action of drugs selected for concurrent use.

Cutaneous mycotic infections caused by filamentous or dermatophytic fungi can be treated either topically or systemically, depending on the location and severity of the skin lesions. Topical antifungal preparations should be

Table 20 Representative ectoparasiticides for application to cattle

Ectoparasiticide class (representative drugs)	Spectrum of activity	Dosage forms (methods of application)
<i>Organophosphate:</i> (Phosmet)	Mites, lice Warble-fly larvae	Solution (pour on)
<i>Pyrethroid:</i> (Cypermethrin) (Deltamethrin) (Fenvalerate) (Permethrin)	Lice, flies	Solution (pour on) Solution (spot on) Liquid concentrate (spray) ^a Ear tag
<i>Amidine:</i> (Amitraz)	Lice, mites, ticks	Liquid concentrate (spray)
<i>Avermectin:</i> (Ivermectin) (Doramectin) (Abamectin) (Eprinomectin)	Mites, lice, Horn fly, Warble-fly larvae	Solution (pour on) Parenteral solution (S.C. injection); Controlled-release ruminal bolus (ivermectin)
<i>Milbemycin:</i> (Moxidectin)	Similar to avermectins	Solution (pour on); parenteral solution (S.C. injection)

^aLiquid concentrates must be appropriately diluted before use.

formulated to promote penetration and persistence of the drug at the site of infection. Drugs that may be applied topically include various imidazole derivatives (clotrimazole, enilconazole, ketoconazole, miconazole), natamycin, nystatin, and tolnaftate, whereas orally administered drugs include ketoconazole, fluconazole, itraconazole, nystatin, and griseofulvin. Superficial infections caused by *Candida* spp. may be treated locally by applying an imidazole derivative or nystatin.

In domestic animals and humans, the common fungal organisms that cause skin infections are *Trichophyton mentagrophytes* (the usual cause of ringworm in calves between 2 and 7 months of age), *Microsporum gypseum*, and *T. verrucosum* (in species other than dogs and cats). Superficial mycotic skin infections are also caused by *T. equinum* (horses, cattle, humans), *M. nanum* (pigs, cattle, humans), and *M. canis* (dogs and cats). Filamentous fungal keratitis in horses is usually caused by *Fusarium* spp. Yeasts, primarily *Candida* spp., can cause mastitis in cows and metritis in mares and occasionally inhabit the skin, primarily at mucocutaneous junctions, in dogs.

For topical application, individual imidazoles and nystatin are formulated as creams, whereas tolnaftate and nystatin are available as ointments. Enilconazole is formulated as a liquid concentrate, that must be diluted before topical application by wash to horses and dogs or by spray to cattle. Topically applied enilconazole may be used in conjunction with systemic (oral) treatment with griseofulvin. Ketoconazole alone and miconazole nitrate combined with chlorhexidine gluconate are commercially available as shampoos for dogs. After topical application, imidazoles attain effective concentrations and persist in the outer layers of the epidermis, and percutaneous absorption appears to be minimal. Natamycin is commercially available as a suspension, to be diluted before application by spray to horses or cattle. In addition to spraying horses affected with ringworm, all grooming utensils and tackle must be thoroughly cleansed and immersed in the natamycin suspension, which should be diluted in plastic or galvanized containers. Natamycin (5% aqueous suspension) is effective in the treatment of filamentous fungal keratitis, particularly when caused by *Fusarium* spp. in horses.

The selectivity of action of antifungal azoles is attributed to their greater affinity for fungal than for mammalian cytochrome P450 enzymes. Because imidazole derivatives (clotrimazole, enilconazole, ketoconazole, miconazole) are less selective in their action than are triazoles (itraconazole, fluconazole), the former subgroup would be expected to cause greater interference with the biosynthesis of endogenous steroid hormones and to show a higher incidence of pharmacokinetic interactions with

other drugs that undergo microsomal-mediated biotransformation.

The therapeutic effectiveness of topically applied corticosteroids is attributed primarily to their anti-inflammatory activity. The relative efficacy of topical corticosteroids appears to be in the following order: hydrocortisone, prednisolone, betamethasone < hydrocortisone valerate or butyrate, betamethasone valerate, triamcinolone acetonide, flucinolone acetonide < betamethasone dipropionate, fluocinonide. In addition to the nature of the corticosteroid, its solubility, and, to a lesser extent, the concentration used, clinical efficacy is influenced by the formulation of the preparation. Glucocorticoids appear to have greater efficacy when formulated in ointment bases than in cream or lotion vehicles. This could be attributed to the occlusive effect provided by ointments. The application of an occlusive dressing further enhances penetration and persistence of the steroid (reservoir effect) in the stratum corneum (112, 128).

TRANSDERMAL THERAPEUTIC SYSTEMS

A transdermal therapeutic system is a rate-controlled drug-delivery system that, applied to the surface of the skin, continuously releases the drug at a rate that will provide a desired steady-state plasma concentration for a specified duration.

The transdermal therapeutic system containing fentanyl [μ (primarily)-opioid agonist], which was designed to release the drug at a constant rate for 72 h, may have application in dogs for the control of postoperative (surgical) pain. Secure placement of the transdermal system that releases 50 μg of fentanyl/h on the dorsal aspect of the thorax of Beagle dogs (11.4–16.5 kg body weight) provided an average steady-state plasma fentanyl concentration of 1.6 ng/ml, which is within the range of plasma concentrations (1–2 ng/ml) considered to provide analgesia without producing other significant effects (129, 130). A steady-state concentration of fentanyl in plasma was reached at approximately 24 h after placement of the transdermal system, as would be expected because the half-life of fentanyl in Beagles is 6 h and was maintained until removal of the system at 72 h. Because the dosing rate ($3.7 \mu\text{g/h} \times \text{kg}$) exceeded the systemic clearance ($2.7 \mu\text{g/h} \times \text{kg}$) and the transdermal bioavailability of fentanyl is 64%, a fraction of the released drug either persists in the stratum corneum or is metabolized in the epidermis before absorption into the systemic circulation, or both may contribute to incomplete systemic availability of the drug. Because of the 24 h delay in achieving plasma

concentrations within the analgesia-producing range, either an intravenous dose (approximately 30 µg/kg) could be administered at the time of placement of the transdermal system or the system could be securely placed on the animal 12 h before performing the surgery.

Whenever a drug-delivery device such as an insecticidal collar or a transdermal system is securely placed on an animal, the increased potential for drug interaction must be kept in mind at the time of selecting another drug for administration by any route and throughout the course of therapy.

Viral Inactivation Issues in Aseptically Processed Parenterals

INTRODUCTION

Plasma-derived therapeutic proteins are parenteral biologics that are purified on an industrial scale. All biologics derived from human sources, such as plasma, carry the risk of viral contamination. Thus, in order to market a medicinal product derived from human plasma, manufacturers must assure the absence of specific viral contamination. Virus validation studies are performed to evaluate the capacity of a manufacturing process to remove viral contaminants. Virus clearance across three different terminal inactivation steps, low pH incubation of immunoglobulins (IgG), pasteurization of albumin, and freeze dry/dry heat treatment of plasma-derived products (Factor VIII and Protein G), is discussed in this article. The data show that, like all other upstream virus reduction steps, the methods used for terminal inactivation are process and product dependent, and that the reduction factors for an individual step may be overestimated or underestimated due to inherent limitations or inadequate designs of viral validation studies.

Parenteral drugs are medicinal products that are not ingested but are injected through the skin, directly into a blood vessel, organ, tissue, or lesion. Since the normal body defenses against infection are bypassed during parenteral administration, preparation of these drugs requires the highest level of contamination control. Contamination can be controlled by terminal sterilization or by aseptic processing. Terminal sterilization involves filling final containers with product and sealing them under a high quality, but not necessarily sterile environment. The product in its final container is then subjected to a sterilization process. During aseptic processing, the product, container, and closure undergo separate sterilization processes and are then brought together. Since microorganisms may be inadvertently introduced during filling, these operations must be performed under stringent conditions to minimize the risk of microbial contamination (e.g., operating in a clean room environment, implementing environmental monitoring programs, and training personnel in aseptic techniques).

Plasma-derived therapeutic proteins are parenteral biologics that are purified on an industrial scale. Most

biologics are highly complex, heat-sensitive, protein mixtures that cannot be terminally sterilized and must be aseptically processed. In addition, all biologics derived from human sources, such as plasma, carry the risk of viral contamination, as the use of plasma-derived products has resulted in the transmission of hepatitis and AIDS. Thus, in order to market a medicinal product derived from human plasma, manufacturers must assure the absence of microbial, as well as specific viral contamination.

Viral contamination of complex biologics can be minimized by strict control of the source material (plasma) and the production process. Controlling the source material involves donor selection, rigorous testing of plasma for virus markers, and inventory hold (Fig. 1). Screening of plasma donors begins with a detailed health questionnaire to identify high-risk factors (e.g., family history of Creutzfeldt–Jakob disease) and behaviors (e.g., tattoos), followed by a physical exam and a background check against the National Donor Deferral Registry (NDDR). Source plasma collected by plasmapheresis (i.e., clear liquid remaining after removal and reinfusion of red cells, leukocytes, and platelets back to the donor) from qualified donors, rather than recovered plasma (i.e., plasma removed from entire blood donations) is used. Qualified donors are those applicants who have successfully passed two donor screenings and testing for viral markers within 6 mo. If a donor does not return to donate within 6 mo, the previous plasma donation is destroyed. Plasma units from applicants who are disqualified on the basis of test results are also destroyed and the names of the rejected donors are entered into the NDDR, a national database that lists all donors who are excluded from further donations.

BACKGROUND

Plasma inventory hold refers to the withholding of all plasma units from qualified donors for 60 day. If a donor, on a repeat visit, shows evidence of viral infection (e.g., seroconversion) or indicates involvement in potential high-risk activity, the donor's previous units held in inventory can be retrieved and destroyed.

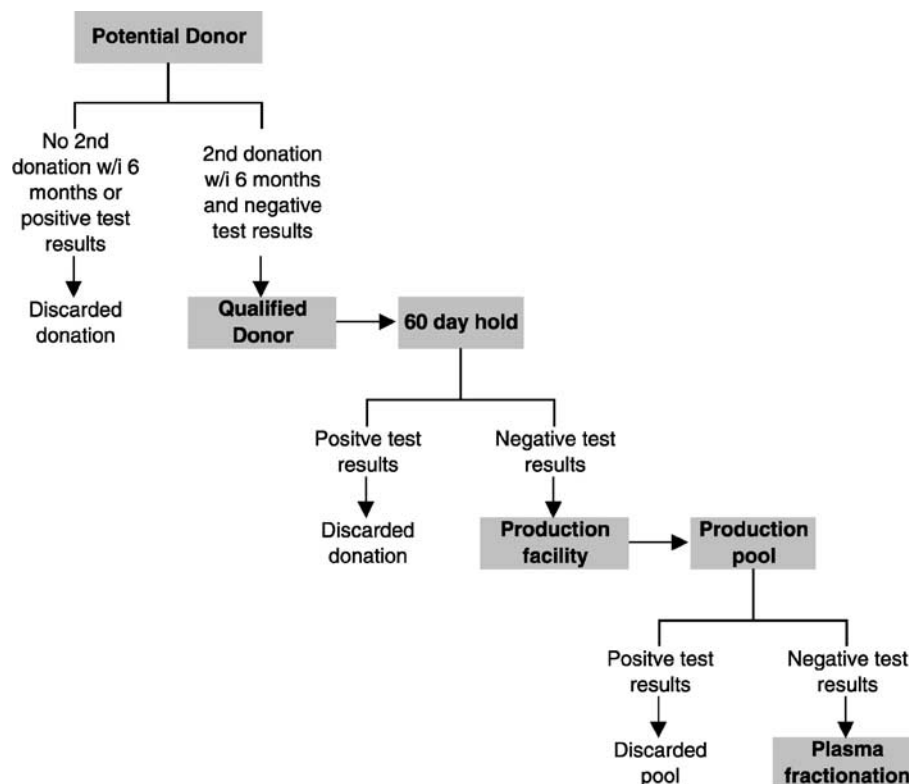

Fig. 1 Controlling source material by the screening and testing of plasma.

All donations must be tested and found nonreactive for syphilis, hepatitis B surface antigen (HBsAg) and negative for antibodies (Ab) to human immunodeficiency virus (HIV) types 1 and 2, and hepatitis C virus (HCV). Many manufacturers are also testing all plasma donations that are negative by standard serological testing, by nucleic acid amplification techniques (NAT) for the presence of viral genomes such as HCV, HIV-1, hepatitis B virus (HBV) and parvovirus B19. Plasma units that are NAT reactive for HCV, HIV-1 and HBV or contain high levels of parvovirus B19 DNA are discarded.

The plasma units that meet viral testing standards by NAT are pooled at the production facility and the pools are retested for the presence of selected viral markers (e.g., HBsAg, Ab to HIV-1/2 and HCV, and HCV RNA). Thus, all source material is screened to reduce or to confirm the absence of many clinically relevant viruses and to minimize any potential viral challenge to the production process.

During the production process, plasma is fractionated or separated into fractions with different biological functions. Because of the complex mixture of proteins, the inability to apply terminal sterilization and the need for tight control of source material, the entire manufacturing

process must follow current good manufacturing practices (cGMP). Biological products are defined more by their manufacturing processes, rather than by analytical testing of final product, to assure the final product is pure, potent, stable, free of microbial contamination, and carries a low risk of viral contamination.

Virus validation studies are performed to evaluate the virus reduction capacity of a manufacturing process and a number of regulatory guidance documents have been issued that describe how to perform and interpret virus clearance experiments.^[1,2] During these studies, production product intermediates are spiked with significant amounts of virus, the material is processed and virus reduction is measured by comparing the level of virus infectivity remaining in the final product-containing fraction with that in the starting material. Process validation is usually performed using the same type and size of equipment that will be used at commercial scale. However, the deliberate contamination of the designated manufacturing equipment and facility with infectious virus would be unacceptable. As a result, virus validation studies are conducted using small-scale replicas and processing conditions representative of production scale.

Reduction, across individual steps of a process, is expressed on a logarithmic scale because virus validation studies can only assure reduction of the virus load by a certain factor. Total reduction of the virus load to zero cannot be guaranteed. The removal/inactivation of the input virus load to below detection or the reduction of $4 \log_{10}$, or more, virus is considered significant. Virus reduction factors for process steps that clear the entire input virus load to below detection, are distinguished from virus reduction factors for steps whose final fractions still contain infectious virus, by the symbol " \geq ." For example, a virus reduction factor of $\geq 3.7 \log_{10}$ would indicate that no infectious virus was detected in the final fraction and that virus reduction could have been greater than $3.7 \log_{10}$ if the input virus spike had been greater. A virus reduction factor of $4.3 \log_{10}$ means a process step cleared significant levels of virus but residual virus could be detected in the final product-containing fraction.

The overall virus reduction capacity of a manufacturing process is the sum of the individual reduction factors, and should be greater than the potential virus load in the starting material. At least one step in the process should clear significant levels of infectious virus so that the overall clearance is not made up of individual small, and possibly negligible, reductions.

Virus reduction steps may be placed upstream or at the very end of the manufacturing process. Reduction in viral infectivity occurs by inactivation of virus or by removal of virus particles. During removal steps, virus is not inactivated but is separated from the protein of interest using methods such as precipitation, chromatography, or filtration. For example, during an ethanol precipitation step, ethanol is added to a suspension to precipitate unwanted contaminating proteins and viruses. The ethanol-containing suspension is then centrifuged so that the contaminants in the precipitated paste fraction can be separated from the product in the effluent fraction.

During inactivation steps, viral infectivity is reduced by treatment with chemicals and/or physical methods. Remnants of virus particles (e.g., viral nucleic acids) may remain in the product-containing fraction but are not infectious. Chemical methods of virus inactivation, such as treatment with solvent-detergent or acetone, must be placed upstream, since subsequent steps are needed to remove or reduce the levels of the toxic chemicals. Terminal inactivation is often achieved using physical methods, such as heat and low pH, because these methods leave no chemical residues. After treatment, the final products are delivered to patients, so aseptic processing conditions must be maintained throughout terminal inactivation steps and the parameters for virus inactivation must be balanced with the conditions to preserve product quality and yield.

The focus of this article is to discuss virus reduction issues that arose during studies of three different terminal inactivation steps: low pH incubation of immunoglobulins (IgG), pasteurization of albumin, and freeze dry/dry heat treatment of plasma-derived products (Factor VIII and Protein G). The data show that, like all other upstream virus reduction steps, the methods used for terminal inactivation are process and product dependent, and the reduction factors for an individual step may be overestimated or underestimated due to inherent limitations or inadequate designs of viral validation studies.

SELECTION OF VIRUSES FOR VIRUS VALIDATION STUDIES

A major issue in performing virus validation studies is determining which viruses should be used. The Committee for Proprietary Medicinal Products (CPMP) has issued guidelines on the selection of viruses to evaluate in validation studies.^[1] Processes must be validated for their capacity to inactivate/remove relevant viruses, or viruses that are known to contaminate plasma or other materials in the production process. If relevant viruses cannot be easily propagated in cell culture or assayed, then validation studies should include specific model viruses with characteristics similar to relevant viruses. If relevant viruses do not represent viruses with a wide range of physico-chemical properties, then validation studies should also include nonspecific model viruses with many different properties. Inactivation/removal of these nonspecific model viruses provides assurance that the manufacturing process is capable of clearing a diverse range of known and unknown viruses.

The virus reduction studies of the three process steps discussed here were performed with HIV-1, Bovine viral diarrhea virus (BVDV), Pseudorabies virus (PRV), Reovirus type 3 (Reo), Hepatitis A virus (HAV), and Porcine parvovirus (PPV). HIV-1 was included as a relevant enveloped virus, while BVDV and PRV were tested as specific model viruses for HCV and HBV, respectively (Table 1). Reo was chosen as a nonspecific model nonenveloped virus, HAV was included as a relevant virus and PPV was used as a surrogate for human parvovirus B19. All viruses were propagated using standard cell culture conditions.^[3,4] The appropriate cell lines were infected, at a low multiplicity of infection, and incubated until 4+ cytopathic effects were observed. The infected cells were frozen and thawed three times to release virus, centrifuged at low speed to remove cell debris and the clarified supernatants were removed for use as virus spikes.

**Table 1** Test viruses

Characteristic	Enveloped viruses		
	Human immuno-deficiency virus (HIV)	Bovine viral diarrhea virus (BVDV)	Pseudorabies virus (PRV)
Relevant or model for Strain	HIV-1, HIV-2 (III B)	HCV Kentucky-22 (BRFF)	CMV, EBV, HSV, HBV PRV dl tk (ATCC VR-2074), Becker (Dupont/Merck)
Nucleic acid	RNA	RNA	DNA
Enveloped	Yes	Yes	Yes
Size (nm)	80–130	80–100	120–220
Resistance to physico-chemical agents	Low	Medium	Medium
	Nonenveloped viruses		
	Reovirus type 3 (Reo)	Hepatitis A virus (HAV)	Porcine parvo virus (PPV)
Relevant or model for Strain	Nonenveloped virus Abney (ATCC VR 232)	HAV HM175 18f (ATCC)	Human parvovirus B19 NADL-2 (ATCC VR 742)
Nucleic acid	RNA	RNA	RNA
Enveloped	No	No	No
Size (nm)	60–80	27–32	18–26
Resistance to physico-chemical agents	High	Very high	Very high

Terminal Inactivation Step: Low pH Final Container Incubation of IgG

Although the partitioning of viruses during ethanol fractionation and the presence of neutralizing antibodies are thought to be the main factors involved in establishing the safety of immunoglobulins,^[5] transmission of HCV by intravenous immunoglobulin (IVIg) has been reported.^[6] Many IgG preparations are formulated at low pH and held for extended periods. The low pH hold step was originally designed to stabilize IgG, reduce anticomplement activity, and allow for intravenous administration.^[7,8] Virus validation studies showed incubation at low pH also inactivated significant levels of enveloped viruses.

The three human IgG products discussed here were purified from Fraction II + III paste by slightly different processing methods but all three shared the same final formulation in 0.2 M glycine, pH 4.25. All three were 10% protein solutions, of which 98% was IgG, and their monomer contents were greater than 90%. At production scale, IgG final bulks (pH 4.25) are typically sterile filtered, aseptically filled into sterile final containers and incubated at 20–27°C for 21 days–28 days.^[9] For the virus studies, however, IgG final bulk material was spiked with virus and adjusted to pH 4.3 or 4.5 before incubating at 5, 20, or 23°C, for up to 28 days. Hanks' Balance Salt Solution (HBSS) or IgG, adjusted to pH 7, were also spiked with virus and included as positive controls.

Aliquots for virus titration were removed on day 0 and at various times during incubation.

The extent and kinetics of reduction were dependent on the test viruses and the exact processing conditions (e.g., pH, time, and temperature). Virus inactivation was greater with lower pH, higher temperatures and longer incubation times and the kinetics of HIV-1 and PRV inactivation were more rapid than BVDV. HIV-1 and PRV were always inactivated to below detection after incubating for 14 days at low pH, 20–23°C but the kinetics of inactivation were slightly different in different IgG solutions (Fig. 2 and Table 2). The entire input load of HIV-1 or PRV was inactivated sooner in IgG solution 1 than in IgG solutions 2 or 3. HIV-1 was below detection after 21 days in IgG solution 1, regardless of pH and temperature, but significant levels of infectious virus were still present after 21 days in IgG solution 2, pH 7 or 5°C. These discrepancies could be due to minor differences in pH (pH 4.3 vs. pH 4.5), temperature (23°C vs. 20°C), or virus preparation.

To control these experimental differences, BVDV inactivation was monitored, in parallel, during low pH incubation, in IgG solutions 1 and 3, using the same stock of virus (Fig. 3 and Table 2). The data show minor changes in pH and temperature resulted in major differences in virus reduction. For example, BVDV reduction in IgG solution 1, 20°C, was 4.2 log₁₀ at pH 4.3 but at pH 4.5, BVDV reduction was only 2.6 log₁₀.

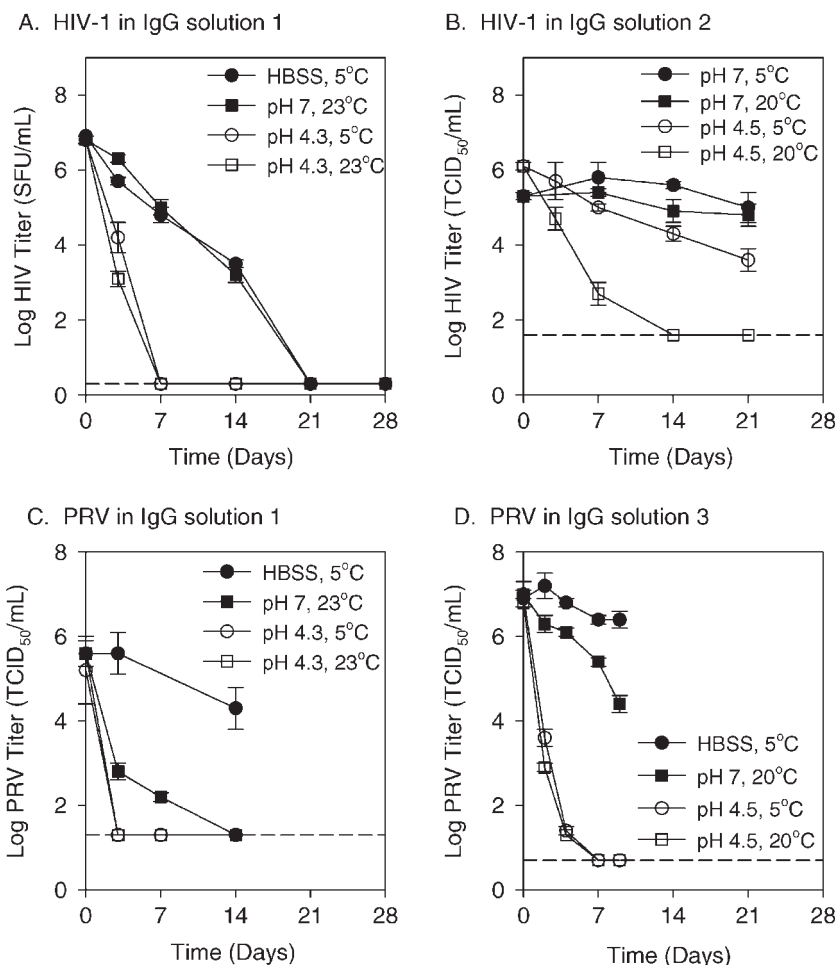

Fig. 2 Kinetics of virus inactivation during low pH incubation in IgG solutions. Virus was spiked into IgG solutions, before adjusting to pH 7, 4.5, or 4.3, and the solutions were incubated at 5, 20, or 23°C. HBSS was also spiked as a positive control. Aliquots for virus titration were removed immediately after spiking ($t = 0$ day) and at various times during incubation. IgG solution 1: HIV-1 (A) or PRV (C), IgG solution 2 or 3: HIV-1 (B) or PRV (D), dashed line, no symbol = virus detection limit.

BVDV reduction was also a function of the IgG test solution. After 21 days in IgG solution 3, pH 4.3, 5°C, no virus could be detected but approximately 4 log₁₀ BVDV was still present in IgG solution 1 under the same conditions. For IgG solution 1, significant BVDV reduction (4.2 log₁₀) was observed at pH 4.3 at 20°C and 23°C but at pH 4.5, less than 4 log₁₀ inactivation was achieved. In contrast, significant BVDV reduction (greater than 4 log₁₀) was observed in IgG solution 3 at both pH 4.3 and 4.5, regardless of temperature.

The results are consistent with other studies in demonstrating the effectiveness of low pH incubation to inactivate enveloped viruses. After incubating IVIg (6% protein, 8% sucrose) at pH 4.4 for one week at 35°C, or for four weeks at 23°C, ≥ 6 log₁₀ Vesicular Stomatitis Virus (VSV) was inactivated.^[10] IVIg (8% protein, 16% maltose) incubated at pH 4 (in the presence of pepsin) for 22 hr at

35°C inactivated mumps, Semliki Forest Virus (SFV), Herpes simplex virus (HSV), and vaccinia virus but had no effect on the nonenveloped poliovirus type 2.^[11] IVIg (7–8% protein, glucose-containing buffer) at pH 4.25 (in the presence of pepsin), 37°C, for 30 hr inactivated HIV, PRV, and BVDV to below detection.^[12]

Immunoglobulins are biologics that differ in many respects from classically synthesized drugs as there are no chemically defined formulas for the many different classes of IgG molecules, each with their own unique antigen recognition capability. Differences in upstream processing may yield product with slightly different protein profiles and these changes could impact virus reduction. For example, in the studies presented here, IgG solutions 1 and 3 were 10% protein solutions with the same formulation but the kinetics and extent of virus inactivation were different in the two products. After incubating at pH 4.5,

Table 2 Summary of virus reduction during incubation at low pH

Test solution	pH	Log ₁₀ virus reduction						
		HIV-1 ^a		PRV ^b		BVDV ^c		
		5°C	20/23°C	5°C	20/23°C	5°C	20°C	23°C

	4.3	■	■	■	■	≥ 4.5	≥ 4.5	≥ 4.4

na = not applicable and gray boxes = not done.

^a HIV-1 studies with IgG solutions 1 and 2 were conducted at different times with different virus stocks and slightly different temperatures. Solution 1 study was 28 days, the incubation temperatures were 5 and 23°C, and titers were calculated as SFU/ml. Solution 2 study was 21 days, the incubation temperatures were 5 and 20°C and titers were calculated as TCID₅₀/ml.

^b PRV studies with IgG solutions 1 and 3 were conducted at different times, using different virus stocks and slightly different temperatures. Solution 1 study was 14 days and the incubation temperatures were 5 and 23°C, while solution 3 study was 9 days and the incubation temperatures were 5 and 20°C.

^c BVDV studies with IgG solutions 1 and 3 were conducted at the same time, using the same virus stock and lasted 28 days.

20°C in IgG solution 3, BVDV inactivation was 4.1 log₁₀ but only 2.6 log₁₀ in IgG solution 1. Significant reduction of BVDV in IgG solution 1 will most likely require incubation at higher temperatures (e.g., 25°C) or lower pH (e.g., pH 4.0). Thus, data which demonstrate the virus safety of a product should not be transferred to other products, even though the two products may appear to be biochemically similar, and each process should be carefully validated.

Terminal Inactivation Step: Pasteurization of Albumin

Pasteurization is the heating of aqueous, stabilized protein solutions. Pasteurization has been used for bulk preparations of Factor VIII, antithrombin III, and alpha₁-antitrypsin but wet heat treatment of these proteins requires the addition of stabilizers that must be removed by a downstream process step.^[13] Removal of stabilizers and denatured proteins from pasteurized materials extends processing times and may involve significant losses in yield.^[14] The development of antibodies to FVIII is a complication of treatment and pasteurization of FVIII concentrates raised concerns regarding the possible induction of FVIII neoantibodies.^[15]

Pasteurizing at 60°C, for 10 hr, in final container, is the pharmacopoeial method to inactivate viruses in albumin preparations. Sodium caprylate and acetyl-tryptophan are often added as stabilizers, which bind to albumin to prevent denaturation or aggregation during heating. So far, only albumin preparations can withstand pasteurization in the final container because the quantity

of caprylate and acetyl tryptophan added are compatible for intravenous administration.^[16] Pasteurization is an effective inactivation step for both enveloped and nonenveloped viruses, as other investigators have shown pasteurization of 20% albumin resulted in ≥ 5 log₁₀ HIV-2, ≥ 7.5 log₁₀ MuLV, ≥ 3.5 log₁₀ PRV, 4.2 log₁₀ Sindbis, ≥ 5.5 log₁₀ Polio, and 6.6 log₁₀ SV40 reduction.^[17] The strongest evidence for safety is in the clinical setting where historical data show that albumin (and plasma protein fraction) solutions have not transmitted viral disease since pasteurization in final container was introduced.^[18]

Evidence for the increased assurance of safety from heating in final container rather than heating in bulk comes from the 1973 outbreak of HBV that was associated with plasma protein fraction (PPF). Investigations revealed that a small amount of PPF had sequestered in a "sampling neck" of a bulk processing container and had not been adequately heated. In contrast, final containers of albumin, made by the same manufacturer, were completely submerged in a waterbath before heating and did not transmit HBV.^[18,19]

The data discussed here are for Plasbumin[®]-25, which is purified from Fraction V paste and consists of 23.5%–26.5% protein, of which no less than 96.5% is albumin. The preparation is stabilized with 0.02 M sodium caprylate and 0.02 M acetyltryptophan and contains 145 mEq/L sodium.^[20] For the virus clearance experiments, virus was spiked into albumin, pH 6.4–7.4, and the solution was heated at 60°C for 10 hr. Aliquots for virus titration were removed as soon as virus was added (preheat), when the temperature of the solution reached 60°C (0 hr) and at

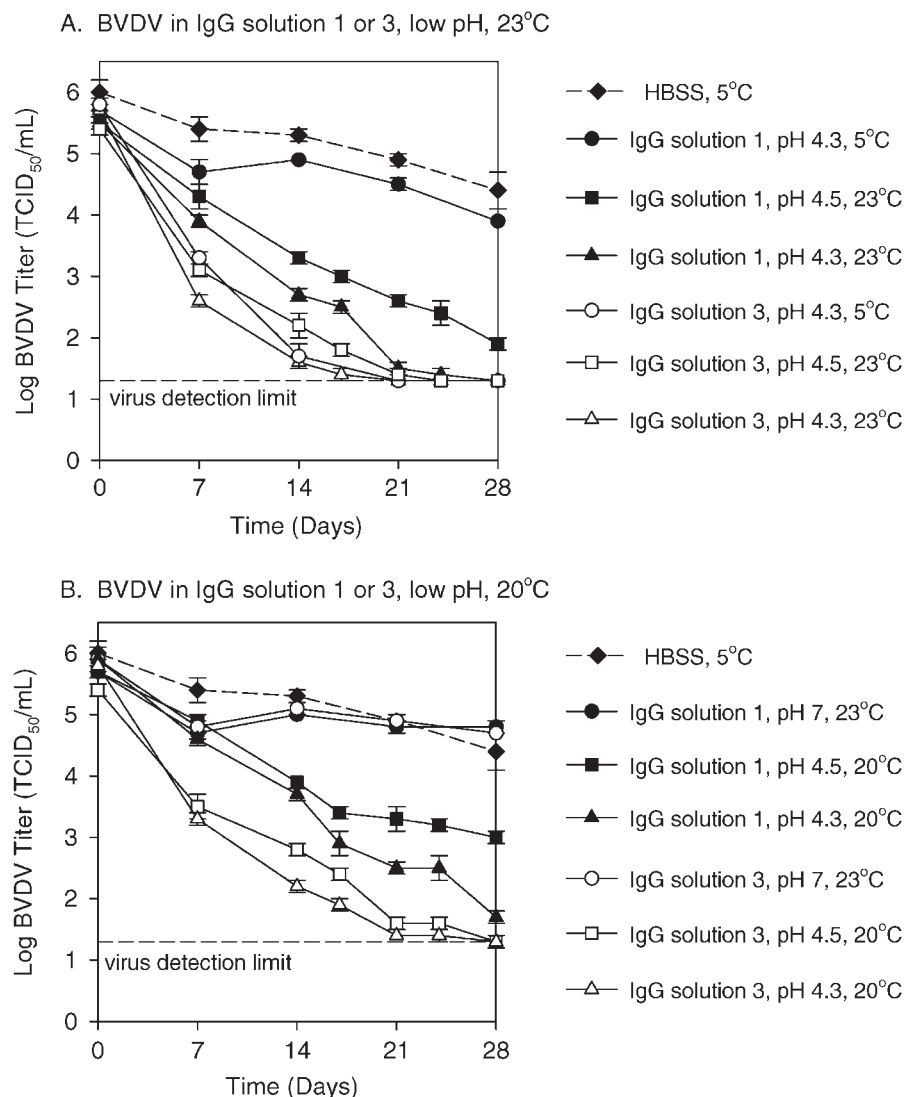

Fig. 3 Kinetics of BVDV inactivation during low pH incubation in IgG solution 1 or 3 at 23°C (A) or 20°C (B). The methods were as described in Fig. 2.

various times during the pasteurization cycle. Unheated albumin and HBSS were also spiked to the same dilution with virus and tested as positive controls.

Enveloped virus inactivation was biphasic, as HIV-1, PRV, and BVDV were quickly inactivated within the first 2 hr of pasteurization. Although inactivation was much slower after 2 hr, all enveloped virus infectivity was below detection after 5 hr (Fig. 4). Although not completely inactivated, the levels of nonenveloped viruses, Reo and HAV (strain HM175/18f), decreased significantly, resulting in 5.6 and 4.4 log₁₀ reduction, respectively (Fig. 4 and Table 3). PPV was the most resistant to pasteurization, as less than 2 log₁₀ virus reduction was observed (Fig. 4 and Table 3).

Additional experiments were performed to examine the robustness of pasteurization to inactivate the most

physico-chemically resistant viruses, HAV and PPV. For these experiments, one parameter (e.g., pH, temperature, or protein concentration) was deliberately set at the extreme limit for processing or set outside normal production processing ranges. All other parameters were maintained at the production setpoints (Fig. 5 and Table 3). The data showed that PPV reduction did not change significantly under any of the conditions tested, while HAV reduction was affected by changes in temperature and protein concentration. When heated below or at the lower limit for temperature, HAV reduction was less than 4 log₁₀. In 25% and 26.5% protein, greater than 4 log₁₀ HAV reduction was achieved but at 5% and 7.5% albumin, HAV reduction was approximately 3 log₁₀. Lower reduction at lower protein concentrations was unexpected since higher concentrations of protein are

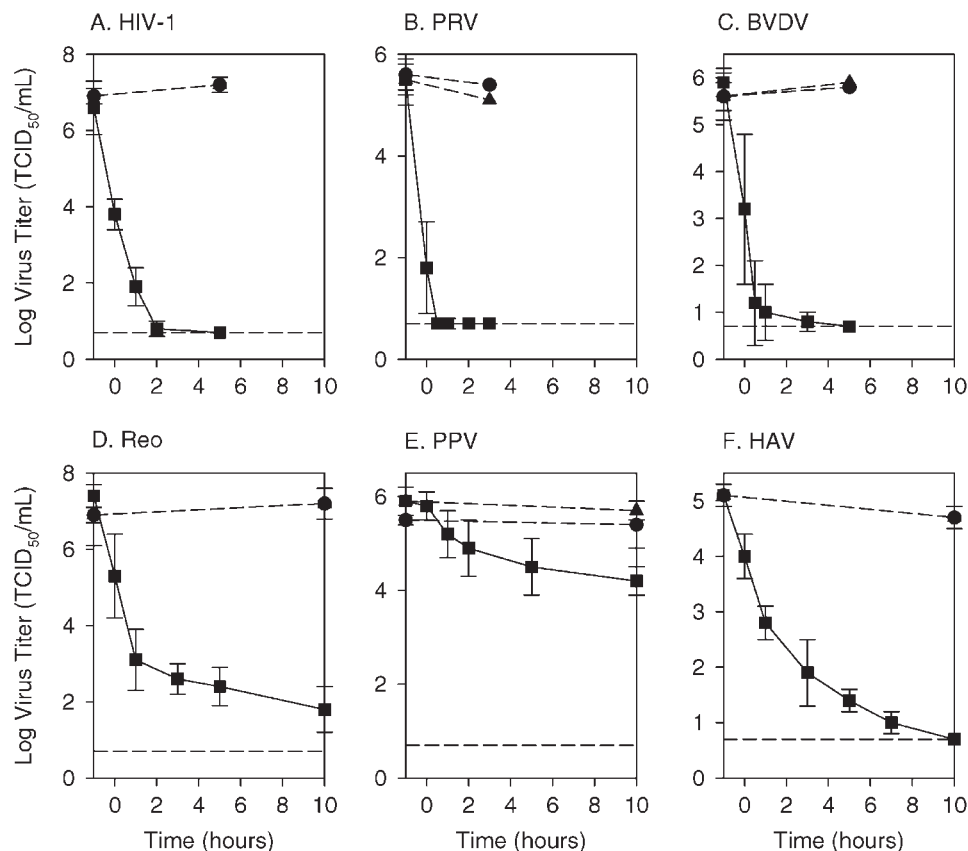

Fig. 4 Kinetics of virus inactivation during pasteurization of 25% albumin. (A) HIV-1, (B) PRV, (C) BVDV, (D) Reo, (E) PPV, and (F) HAV. Virus was spiked into albumin and an aliquot was removed for immediate titration (t = Preheat). Timing of the pasteurization cycle started when the temperature reached 60°C (t = 0 hr). Unheated albumin and Hanks' Balanced Salt Solution (HBSS) were also spiked and incubated at 5°C, as positive controls. Aliquots for virus titration were removed at various times during pasteurization (closed circles = HBSS, 5°C, closed triangles = 25% albumin, 5°C, closed squares = 25% albumin, 60°C, dashed line, no symbol = virus detection limit).

Table 3 Summary of virus reduction during pasteurization of 25% albumin

Test parameter		Log ₁₀ virus reduction					
		HIV-1	PRV	BVDV	Reo	PPV	HAV

Gray boxes = not tested.

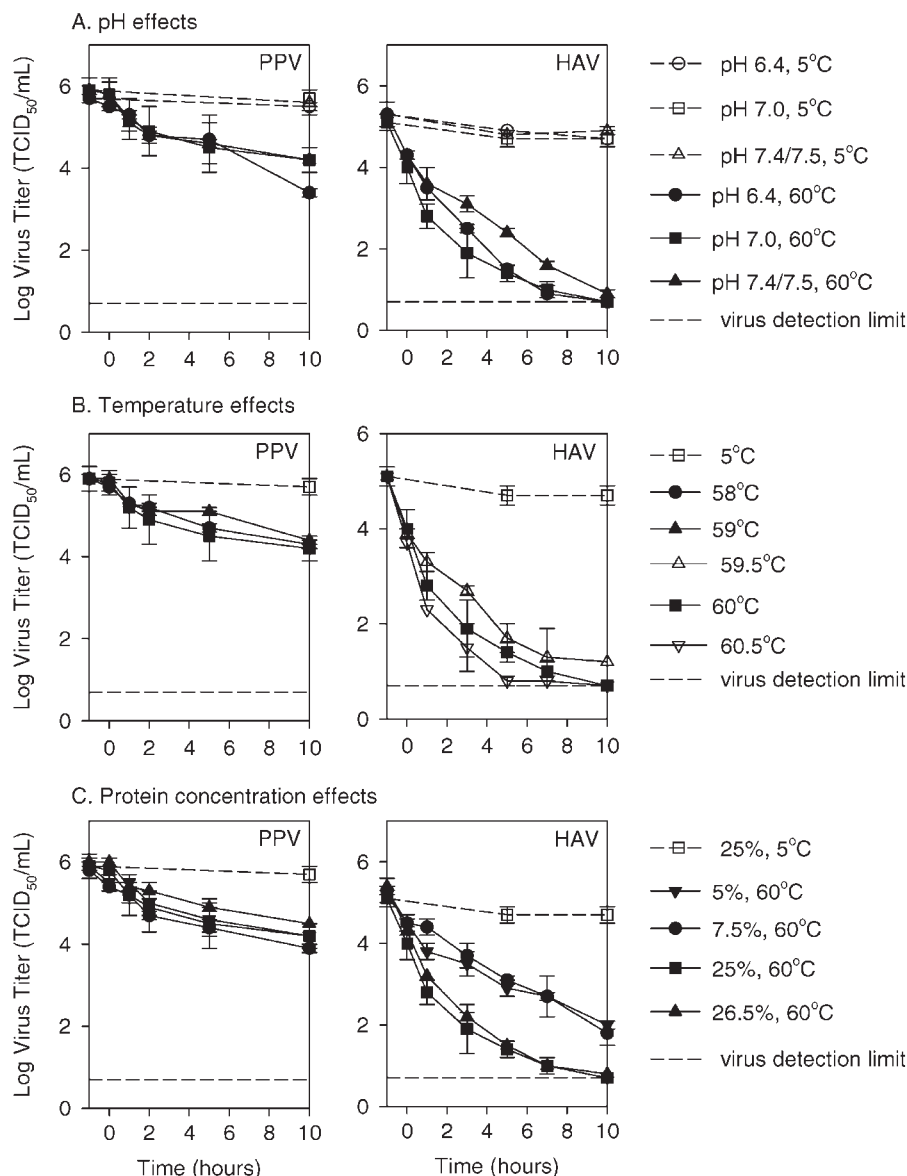

Fig. 5 Effect of (A) pH, (B) temperature, and (C) protein concentration on PPV and HAV inactivation during pasteurization of 25% albumin. Methods were as described in Fig. 4, except different pH, temperature, or protein concentrations were tested.

expected to provide virus with better protection from physico-chemical treatments than lower concentrations. The ratio of stabilizer to protein is the same for both 5% and 25% albumin. However, since 25% albumin contains five times more protein than 5% albumin, the concentrations of stabilizers (sodium caprylate and acetyl tryptophan) are also five times higher. Thus, the discrepancy in HAV reduction in 25% and 5% albumin may be related to the concentrations of stabilizers (or virus destabilizers) in the solutions.

All viruses used in clearance studies are actually model viruses since they have been adapted to grow in cell

culture and laboratory adapted virus strains may be slightly different from clinical isolates. Antigenic and genetic variations have been reported for laboratory adapted strains of HAV.^[21] Two different clones of HAV strain HM175, 18f and 24a, were pasteurized in 25% and 5% albumin and their kinetics of inactivation were compared. The results show HAV HM175/18f was much more resistant to pasteurization than HAV HM175/24a (Fig. 6, Table 4). The titers of HAV HM175/18f were slightly higher than that in the previous experiment but the extent and kinetics of inactivation were similar. HAV HM175/18f inactivation in 25% albumin was 4.5 log₁₀ but

Fig. 6 Kinetics of HAV strain HM175/18f or HM175/24a inactivation during pasteurization in 25% or 5% albumin. The methods were as described in Fig. 4.

was 3.1 \log_{10} in 5% albumin. Inactivation of HAV HM175/24a was not significantly affected by protein concentration, as 4.2 \log_{10} reduction was observed during pasteurization in both 25% and 5% albumin.

Laboratory adapted strains of HAV are often associated with cellular membranes. Propagation of HAV involves freezing and thawing of infected cells to release virus. During its release from disrupted cells, virus may become entangled or associated with cellular membranes, which may shield virus from neutralization by antibody.^[22] To determine if cell associated lipids protect virus from heat denaturation, HAV HM175/18f was extracted with chloroform and inactivation of the extracted virus and untreated virus, during albumin pasteurization, was compared. The results show inactivation of chloroform-extracted virus was significantly faster than untreated virus (Fig. 7).

PPV was also extracted with chloroform, but chloroform extraction had little effect on PPV inactivation during albumin pasteurization (Fig. 7). These results are comparable to previous reports of only 1–2 \log_{10} Minute Virus of Mice, another parvovirus, inactivation after 6 hr of pasteurization in 1% albumin.^[23] Thus, heat stability during pasteurization may be a parvovirus-specific trait,

which is not due to virus association with cellular membranes.

In summary, pasteurization is effective for inactivation of many enveloped and nonenveloped viruses but their kinetics of inactivation are different. In the experiments with 25% albumin, enveloped viruses were below detection after heating for 5 hr, leaving a wide margin of safety. In contrast, nonenveloped virus reduction was slower and required the entire 10 hr of heating. Temperature, time, protein concentration, and possibly stabilizers were critical parameters for virus inactivation.

The data also demonstrated that the subtle differences in viruses should not be underestimated. The different HAV strains/clones and the method of virus preparation had a significant impact on virus clearance. Virus stocks used in virus validation studies are produced in cell culture and the behavior of tissue culture derived viruses may be different from that of native viruses. Laboratory adapted strains of viruses may also have unpredicted properties, such as association with lipids, which may affect their properties. Regardless of the panel of test viruses used in clearance studies, all virus stocks used should be strictly controlled and produced from qualified and traceable cell lines and virus seed banks. Repeated passage of the original stock virus is not recommended because mutations and deviations from the original reference material can result.

Table 4 HAV reduction during pasteurization in albumin

5% albumin	3.1	4.2

Terminal Inactivation Step: Dry Heat Treatment of Freeze Dried Product

Proteins undergo chemical (e.g., deamidation or oxidation) and/or physical degradation (e.g., aggregation and precipitation) in aqueous solutions. Many of these

Fig. 7 Effect of chloroform extraction on virus inactivation during pasteurization in albumin. For these experiments, the virus spike was divided into half. One-half was extracted with an equal volume of chloroform while the other-half was prepared as usual. The untreated and chloroform extracted virus were then used as virus spike in pasteurization experiments as described in Fig. 4.

destabilizing reactions are minimized when water is removed and proteins remain in a dried solid state. This process of removing water from the product is called freeze drying or lyophilization, and is an effective way to improve the stability and extend the shelf-life of labile proteins. During the freeze drying step, final containers are aseptically filled, the product is frozen and then the frozen solid is dried by the sublimation of ice under vacuum.

Many freeze dried coagulation concentrates are heated to reduce the risk of virus transmission. During terminal dry-heat treatment, freeze dried FVIII concentrate in final container is heated for periods ranging from several minutes to several days at temperatures ranging from 60 to 100°C.^[4,24–26] This method was originally developed to inactivate hepatitis viruses^[27] but was later recommended by the National Hemophilia Foundation^[28] and the Centers for Disease Control^[29] to reduce the transmission of HIV.

Process validation associated with a freeze dried/dry heated product is more challenging than for products with liquid formulations for some of the following reasons:

1. Assuring specified fill volumes is difficult because many formulations consist of small amounts of the active agent and large amounts of stabilizers. Unlike a powder or liquid fill, a low fill is not readily apparent after freeze drying.
2. The number of variables to ensure aseptic processing is high. Before aseptic fill, different parts of the final product must be sterilized by different methods, such as dry heat to sterilize and depyrogenate glass containers, autoclaving and drying to sterilize and remove moisture from rubber stoppers, and sterile filtration for the liquid formulated product. After aseptic fill, the stoppers are placed on top of the vials

and the partially stoppered vials are transported, loaded into a freeze dryer, and then freeze dried. During freeze drying, the sterilized material in the vials in the freeze dryer will be exposed to the chamber's nitrogen or air, so bacterial retentive filters must be used in all vacuum/air lines to the chamber. Thus, the risk of contamination exists throughout the process until the vials are actually stoppered at the end of the freeze drying cycle.

3. Equipment reuse also carries a risk of contamination, so cleaning procedures for freeze dryers should be validated for their effectiveness to inactivate virus.
4. The technology for freeze drying/dry heat treatment is complex and there are many process parameters to control (e.g., temperatures of the shelf, product and condenser; freezing and drying rates; pressures of the chamber and condenser; and temperature and distribution of heat in the oven).

A process step with many variables to control is equally difficult to scale down for bench scale studies. However, results from animal studies and human clinical trials have been consistent with the “in vitro” model virus clearance studies of the terminal freeze dry/dry heat treatment.

1. Virus clearance studies of Factor VIII (Hemofil T) indicated the freeze dry/dry heat treatment (60°C, 72 hr) step was effective in inactivating HIV (≥ 3 log₁₀ HIV-1 reduction), but was less effective for HBV-like viruses (> 1 log₁₀ PRV reduction, 2.4 log₁₀ VSV reduction) and for HCV-like viruses (2.9 log₁₀ Sindbis reduction).^[30] Studies in animals and humans confirmed the model virus results. Chimpanzees inoculated with Hemofil T, that had been spiked

with HBV (30,000 chimpanzee infectious doses) and freeze dried/dry heated, later developed hepatitis B.^[27] During clinical trials, none of the patients treated with heated Hemofil T became HIV-1 positive^[31] but 11 out of 13 patients developed non-A, non-B hepatitis.^[32]

2. Virus clearance studies of a solvent/detergent treated, freeze dried/dry heated (100°C, 30 min) Factor VIII concentrate (Emoclot), demonstrated significant inactivation of HAV and poliovirus 1 by the terminal freeze dry/dry heat step.^[24] No model parvovirus was included as a test virus in these in vitro studies. During clinical trials, 13 previously untreated patients were given Emoclot and none of them became anti-HAV positive. In contrast, B19 seroconversion and viremia was observed in 5 of 11 susceptible patients.^[33]

Koate®-DVI is a freeze dried concentrate of human plasma-derived Factor VIII (FVIII) that is stabilized

with albumin (10 mg/ml) and formulated in a buffer containing 0.05 M glycine, 3 mM calcium, 0.06 M histidine.^[34] After freeze drying, it is terminally heated in final container for 72 hr at 80°C. Water molecules normally help to maintain proteins in their native state but, in freeze dried material, water molecules may contribute to degradative reactions. The following studies were performed to demonstrate that controlling residual moisture levels in freeze dried/ dry heated cakes may be a method for achieving viral inactivation in the Koate-DVI process.^[4]

Vials of virus-spiked FVIII were freeze dried, sealed with stoppers containing different amounts of moisture, and then heated at 80°C for various times. Moisture in the virus-spiked samples was monitored by Near InfraRed (NIR) spectrometry, whose values had been correlated to loss on drying (LOD) moisture values.^[37] After converting the NIR values to LOD moisture levels, the freeze dried/dry heated materials were reconstituted and titrated for residual virus.

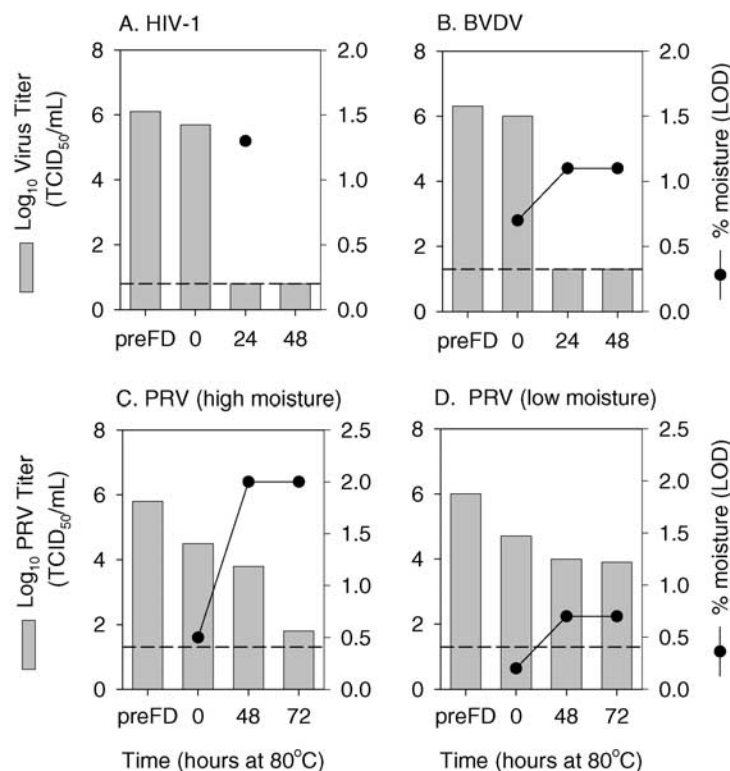

Fig. 8 Kinetics of enveloped virus inactivation during 80°C heat treatment of freeze dried Factor VIII (FVIII) concentrate. (A) HIV-1, (B) BVDV, (C) PRV (> 0.8% moisture) and (D) PRV (< 0.8% moisture). Virus was spiked into FVIII concentrate and a sample was immediately removed for virus titration (pre-FD). Vials were aseptically filled with virus-spiked FVIII concentrate and then freeze dried. After freeze drying, the vials were closed, using stoppers containing different levels of moisture, and sealed before heating at 80°C for up to 72 hr. Near infrared (NIR) readings were taken on vials after freeze drying (0 hr) and at various times after heating at 80°C (24 hr, 48 hr, or 72 hr). After converting the NIR readings to loss on drying (LOD) moisture values, the product in each vial was reconstituted and assayed for residual virus (gray boxes = log₁₀ virus titer, closed circles = % moisture, and dashed line = virus detection limit).

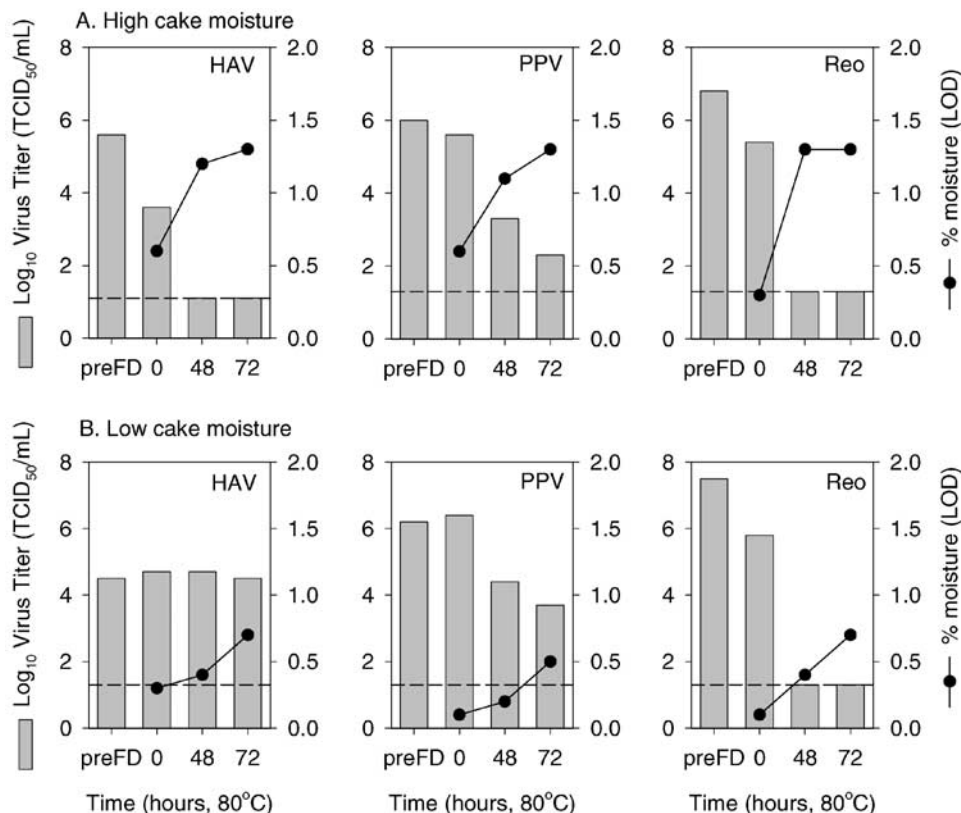

Fig. 9 Kinetics of nonenveloped virus inactivation during 80°C heat treatment of freeze dried Factor VIII (FVIII) concentrate (A) in the presence of high cake moisture (> 0.8% moisture) or (B) in the presence of low cake moisture (< 0.8% moisture). Methods were as described in Fig. 8 (gray boxes = log₁₀ virus titer, closed circles = % moisture, and dashed line = virus detection limit).

As shown in Figs. 8 and 9, the moisture content in freeze dried material was not constant after freeze drying. Autoclaved rubber stoppers hold measurable amounts of water that are transferred to the freeze dried

product^[35,36] and heating at 80°C accelerates this transfer.

Virus reduction data are presented in Figs. 8 and 9 and Table 5. Little or no HIV, BVDV and PPV reduction

Table 5 Summary of virus reduction during 80°C heat treatment of freeze dried AHF

	HIV-1		BVDV		PRV	
	Log ₁₀ virus reduction ^a	Moisture ^b	Log ₁₀ virus reduction	Moisture	Log ₁₀ virus reduction	Moisture
Enveloped viruses						
Low moisture	≥ 5.3	1.3 (24 hr)	≥ 5.7	1.1 (24 hr)	2.1	0.7 (72 hr)
High moisture	■	■	■	■	4.0	2.0 (72 hr)
	HAV		PPV		Reo	
	Log ₁₀ virus reduction	Moisture	Log ₁₀ Virus Reduction	Moisture	Log ₁₀ Virus Reduction	Moisture
Nonenveloped viruses

High moisture	≥ 4.5	1.3 (72 hr)	3.7	1.3 (72 hr)	≥ 5.5	1.3 (72 hr)

Gray boxes = not tested and methods were as described in Fig. 8.

^aLog₁₀ virus reduction = Log₁₀ total virus_{pre-FD} - Log₁₀ total virus_{post-80°C heat}.

^bFreeze dried product was measured by NIR spectrometry. The NIR values were then converted to LOD moisture values using a NIR/LOD calibration curve.

occurred during the freeze drying process, but PRV, Reo, and HAV titers, before (Pre-FD) and after freeze drying (0 hr), decreased 1–2 \log_{10} . Regardless of moisture content, HIV, and BVDV were inactivated to below detection after heating 80°C, 24 hr, and Reo was completely inactivated after 48 hr. Inactivation of HAV, PRV, and PPV was dependent on the moisture levels in the cake. When the moisture in the system was 0.8% or greater, virus inactivation was approximately 4 \log_{10} . However, when less than 0.8% moisture was present, virus reduction after heating was $\leq 2.5 \log_{10}$.

These data show the freeze dry/dry heat treatment of the Koate®-DVI process can effectively inactivate significant levels of enveloped and nonenveloped viruses if a minimum threshold level of moisture (0.8%) is attained. Increased moisture levels during dry heat treatment also destroys FVIII activity and at 1.6% moisture, the upper limit for moisture at this step, specific activity decreases an average of 11%.^[38] To compensate for the loss in potency, the bulk is made more concentrated to assure FVIII activity at 9 IU – 22 IU activity per mg protein.

Other investigators have also shown parvovirus inactivation by the terminal freeze dry/dry heat (80°C, 72 hr) step. Canine parvovirus, spiked into FVIII concentrate, Replenate®, was inactivated by 3.0 \log_{10} ,

while 4.7 \log_{10} bovine parvovirus spiked into FVIII concentrate, Liberate®,^[39] was inactivated after heating lyophilized product for 72 hr, 80°C. Unfortunately, in these studies, product loss after treatment was as high as 30%.

Although viruses from different animal species (e.g., porcine, canine, and bovine) were used to test the terminal freeze dry/dry heat treatment of the Koate®-DVI, Replenate®, and Liberate® processes, the differences in parvovirus reduction and product recovery were probably due to the different formulations and freeze drying cycles of all three FVIII products. For freeze dried products, formulation and the freeze drying process are interrelated. Without the appropriate buffers and stabilizers or optimal temperatures and cycle times, many protein preparations would be denatured by the physical stresses associated with the freeze dry/dry heat treatment.

The impact of formulation on virus reduction and product recovery (e.g., potency) was evaluated during terminal freeze dry/dry heat treatment studies with an unlicensed Fraction I derived product, that will be designated “Protein G.” As shown in Fig. 10, the optimum formulation, that achieved $\geq 4 \log_{10}$ PPV inactivation and 80% product recovery, was one that contained 2% albumin, no NaCl, and $\leq 0.3\%$ moisture by the Karl Fischer coulometric method. In contrast, freeze

Freeze dried Protein G formulated in buffer

51%		5%		35%		< 2%	
				80%		ND	
				70%		30%	

¹ Low moisture $\leq 0.3\%$ (Karl Fischer coulometric method) after 80°C heat, dry heat, 72 hours

² High moisture $\geq 1.5\%$ moisture after 80°C dry heat, 72 hours

³ Log PPV reduction after 80°C dry heat, 72 hours = Total virus_{pre-FD} – Total virus_{post 80°C heat}

⁴ % potency recovered after 80°C dry heat, 72 hours =

$$[(\text{Potency}_{\text{pre-FD}} - \text{Potency}_{\text{post 80°C heat}}) \div \text{Potency}_{\text{pre-FD}}] \times 100$$

ND = Not Done

Fig. 10 Effect of formulation on virus reduction and product recovery. Protein G was formulated in buffer containing albumin (0% or 2%) and NaCl (0 mM or 150 mM). Virus was added and a sample was immediately removed for virus titration (Pre-FD). The virus-spiked material was aseptically filled into vials, freeze dried, and then heated at 80°C, 72 hr. Mock-spiked Protein G was processed like the virus-spiked samples but was used to measure product recovery (potency).

dry/dry heat treatment of product formulated with no albumin, 150mM NaCl and low moisture resulted in approximately 3 log₁₀ PPV reduction and 35% product recovery. Thus, minor changes in formulations such as the addition of 2% albumin may impact virus reduction and product recovery during a freeze dry/dry heat treatment.

In summary, the large number and complexity of the variables to control when implementing a terminal freeze dry/dry heat treatment makes validation very difficult and increases the probability for error. Since the reliability of the results from virus clearance studies is dependent on the appropriateness of the models used in the studies, it is essential that the freeze dry/dry heated material and the experimental conditions used at small scale be representative of production scale. During the studies, temperature and pressure must be controlled during all stages of the freeze drying cycle and uniform temperatures must be distributed throughout the oven used for the dry heat step. Process parameters such as the amount of moisture retained by rubber stoppers should be examined, as they influence the rate and extent of viral inactivation and the recovery of biological activity.

Perhaps more difficult to duplicate or control during small scale virus clearance studies, are the precise composition and the molecular structure of freeze dried materials. The formulation studies with Protein G indicated virus reduction and product recovery were influenced by the presence of albumin at a prefreeze drying volumetric concentration of 2%. All proteins have unique physico-chemical properties and stabilization requirements, so formulation and freeze drying cycle parameters must be customized for each new protein drug. For terminal viral inactivation steps, it is equally important to develop a formulation and freeze dry cycle that will not stabilize virus.

CONCLUSION

The direct testing for potential viral contamination in a finished product is not considered sensitive or accurate enough to assure the absence of infectious virus because many of the viruses known to contaminate plasma (e.g., HCV, HBV, and parvovirus B19) cannot be easily grown or assayed in cell culture. Testing for the presence of viral nucleic acids in final product is sensitive but cannot distinguish infectious particles from noninfectious particles. Thus, assuring the safety of plasma-derived products with respect to virus transmission is an indirect combinatorial approach: screening and selection of the source material, validation of the production processes for inactivation/removal of virus infectivity, and process control by strict adherence to cGMP.

Screening and selection of the source plasma will only avoid contamination by known pathogens. The protein

purification steps and specific virus reduction methods used in production processes, however, will inactivate and/or remove both known and unknown viruses. Terminal virus inactivation treatments are applied to product in final container and must balance virus inactivation with any modifications to protein immunogenicity, activity, and yield. While many upstream virus inactivation steps rely on chemical methods that involve the addition and subsequent removal of toxic agents (e.g., solvent/detergent), physical methods for virus inactivation, such as pH and heat, are used for terminal steps.

Virus validation studies assess the virus clearance capacity of a process and the evaluation and interpretation of virus clearance data from terminal inactivation and upstream process steps are similar. Limitations in the design and execution of virus validation studies may lead to an incorrect estimate of the ability of a process to inactivate/remove virus infectivity. The three terminal inactivation treatments discussed here illustrate the importance of rigorously controlling virus validation studies.

1. During the low pH incubation step of IgG, minor changes in pH and temperature, as well as in upstream processing steps, significantly impacted the kinetics and extent of virus inactivation. Thus, the process variables evaluated during virus clearance studies must be carefully selected and defined since they may alter the efficacy of the step for virus reduction.
2. The results from the albumin studies demonstrated that virus selection (e.g., HM175/18f and HM175/24a) and preparation (e.g., chloroform extracted and untreated virus) were just as important as the process conditions (e.g., protein concentration and temperature) in determining the outcome of virus reduction during pasteurization. Since laboratory adapted viruses and naturally occurring viruses may differ in their sensitivity to physico-chemical treatments, the results observed with model viruses must be carefully interpreted before they can be extrapolated to relevant viruses of concern.
3. Certain process steps may be easier to model than others and duplicating the freeze dry/dry heat step at small scale is very difficult. The conclusions drawn from virus clearance studies are reliable only when the appropriateness of the small-scale models can be demonstrated. During the freeze dry/dry heat step of Koate[®]-DVI, virus reduction was dependent on moisture levels so even the formulation of stoppers, which could impact the absorption of water during autoclaving and its release to freeze dried material, must be considered and tested.

4. Formulation studies with Protein G suggested that the addition of virus could affect the composition and freeze dry/dry heat treatment of spiked product intermediates. As specified in guidance documents for virus clearance studies,^[1,2] the amount of virus spiked into starting test materials should be as high as possible so that the maximum virus reduction capacity of a production step can be determined. In many clearance studies, the volume of the virus added may be as high as 10%. Since virus reduction and product recovery, during freeze dry/dry heat treatment of Protein G were influenced by the presence 2% albumin, high amounts of virus may alter the composition and structure of freeze dried materials. However, until the analytical tools to study the basic behavior of all proteins during freeze drying and dry heat treatment become available, the stability of viruses and their interactions with plasma proteins will not be fully understood.

The terminal inactivation studies discussed here also demonstrate there is no “magic bullet” to inactivate all viruses. Many inactivation steps are effective against some but not all virus families. Thus, production processes should contain other upstream orthogonal steps to assure broad and effective virus reduction. Regardless of the virus reduction capacity of a manufacturing process, however, absence of virus in plasma-derived products can never be guaranteed because the amount of contaminating virus in source material is generally not known and the presence and/or appearance of new unknown viruses cannot be excluded.

Manufacturing processes have evolved dramatically over the last few years. In the late 1980s, 76% of hemophiliacs were HCV positive,^[40] and between 1979 and 1985, approximately 50% of hemophiliacs had acquired HIV from plasma-derived FVIII.^[41] Since then, however, most U.S.-licensed plasma derivatives have not transmitted HBV, HCV, or HIV as a result of improvements in donor screening and test methods, and the inclusion of effective upstream virus-reduction and terminal virus-inactivation steps in manufacturing processes.^[18] Residual risks of virus transmission from plasma-derived products are now largely associated with nonenveloped viruses.^[42] Thus, the need for additional terminal or upstream virus inactivation/removal steps still exists, but the current challenge is to develop cost effective methods against physico-chemically resistant nonenveloped viruses, such as human parvovirus B19.

Water for Pharmaceuticals

Leonid Shnayder

Aker Kvaerner Pharmaceuticals, Bridgewater, New Jersey, U.S.A.

INTRODUCTION

Water is one of the key utilities in most pharmaceutical facilities. It is used as a solvent, product ingredient, cleaning agent, and for many other applications. Some of those applications require water of higher purity than typically found in municipal water supplies. Therefore companies install private water purification systems that become a critical part of their utility infrastructure.

Why does the potable water from municipal supply require further treatment for pharmaceutical manufacturing? To understand this, let us look into the two main water sources for municipal plants: groundwater aquifers (well water) and surface supplies (rivers and lakes). As rainwater falls onto the Earth's surface, it picks up and dissolves atmospheric gases (oxygen and carbon dioxide), industrial emissions such as nitric and sulfuric oxides, as well as bacteria and dust particles. As it passes through the ground into the aquifers, the water is filtered and becomes quite clean, free of most particles and organic contaminants. However, it now dissolves minerals contained in the limestone and other geological materials. That adds calcium, magnesium, sodium, iron, chlorides, sulfates, and other ions to the ground water. The surface waters found in the lakes and rivers collect organic materials and particles from vegetation and ground runoff.

Municipal water plants provide limited treatment, mostly intended to make the water safe to drink. A lot of contaminants, such as salts, dissolved gases, and organic materials contained in natural sources, remain in the municipal water supply. In addition, chlorine or other disinfectants are often added as part of the treatment process to control microbial contamination. For many critical applications required in pharmaceutical plants, such water quality is not sufficient, and further treatment is necessary.

GRADES OF WATER USED IN THE PHARMACEUTICAL FACILITIES

The water purity required varies widely with the application. For example, water used to feed the boilers producing plant steam only needs to be softened (to avoid scale buildup) and deaerated (to avoid corrosion in the

steam system). On the other hand, water used as an ingredient for an injectable drug has to meet much more stringent quality requirements. The US Pharmacopeia (USP) contains specifications for several grades of water used in the preparation of medicinal products. The two grades most often used in the pharmaceutical plants are USP Purified Water and Water For Injection (WFI). As the name implies, WFI is used for the preparation of injectable drugs, whereas USP Purified Water can be used in the manufacturing of tablets, capsules, creams, lotions, etc. These types of water are called "compendial" because their quality is specified in an official nationally recognized standard such as USP. In addition, many companies use various noncompendial water systems designed for specific needs. While designing the facility, it is important to decide on the proper grades of water to use in various applications. Compendial waters are typically very expensive, not only because of required treatment steps, but also because of extensive validation and testing requirements. Therefore it is prudent to limit their use to processes where such water becomes an ingredient of the pharmaceutical product, is in direct contact with such product, or is used for the final rinse of critical process equipment. For most other applications, various noncompendial grades of water (potable, softened, deionized, etc.) can be successfully used without any regulatory conflicts. It is not uncommon to install a water system that produces water that could easily meet the USP specification yet is not designated as USP Purified Water to avoid unnecessary expenses for regulatory compliance.

The current edition of USP^[1] establishes the following requirements for USP Purified Water:

- Purified Water is prepared from water complying with the federal regulations for drinking water.
- Purified Water contains no added substance.
- Purified Water is obtained by a suitable process.
- Conductivity does not exceed set level (1.3 $\mu\text{S}/\text{cm}$ at 25°C).
- Total organic carbon (TOC) does not exceed set level (500 ppb).

The requirements for WFI are as follows:

- Meets all the requirements for "Purified Water"

- Is obtained by distillation or reverse osmosis (RO)
- Contains not more than 0.25 USP endotoxin units per milliliter
- Is prepared using suitable means to minimize microbial growth.

The USP does not specify allowable concentrations of microorganisms in the official monograph, but recommends action limits of 100 colony-forming units per ml (CFU/ml) for Purified Water and 0.1 CFU/ml for WFI.

Putting aside the items related to the source water and treatment procedures, we can summarize the requirements for Purified Water itself as follows:

1. Low conductivity (high resistivity). This test is intended to show that water contains a minimal amount of ions such as calcium, magnesium, sodium, iron, chloride, sulfate, etc. The inherent presence of hydrogen and hydroxide ions determines the theoretical limit of Purified Water conductivity: approximately 0.05 $\mu\text{S}/\text{cm}$ (resistivity 18 $\text{M}\Omega\text{ cm}$) at a pH of 7.0. The practical limits specified in the USP are in the range of 1–5 $\mu\text{S}/\text{cm}$, depending on pH and temperature.
2. Low TOC (less than 500 ppb). Water shall contain a minimal amount of organic compounds. Such compounds are undesirable for two main reasons: they may be toxic, and/or they may serve as sources of nutrition for microorganisms.
3. Low microbial count. Water shall contain a minimal amount of viable microorganisms, including spores.
4. Low endotoxin level (required for WFI only). The term “endotoxin” applies to organic compounds that cause harmful effects when injected in the bloodstream of laboratory animals. Such compounds are lipopolysaccharides produced as a result of microbial growth or microbial destruction.

WATER PURIFICATION SYSTEMS

As naturally occurring water has a variety of contaminants, there are many treatment processes developed to remove those contaminants. A typical pharmaceutical water purification system contains several unit operations designed to remove various components.

Particle Removal

The municipal water treatment plants use a process called “clarification” based on gravity settling to remove a

majority of the large particles suspended in water. However, some of the suspended materials remain in the potable water and need to be removed as part of the pharmaceutical water purification.

The most common process used for this is depth filtration through a bed of sand or similar material charged in a vertical vessel. The incoming water flows from top to bottom. To improve the efficiency of such filters, two or more layers of media with various particle sizes are used. Coarse and less dense material such as anthracite is located at the top of the bed, whereas finer and denser particles of sand are placed at the bottom. Such multimedia filters can remove most particles larger than 10–20 μm . Periodically the filter bed is backwashed by reversing the flow direction (from bottom to top) and by increasing the flow rate. During backwash, the captured particles are removed and sent to drain, whereas heavier particles of the filter bed remain in the vessel and settle back at the end of the cycle.

In smaller water purification systems, we can often find a cartridge-type depth filter used for the particle removal. The cartridge is made of cellulose, cotton, or polymer fibers, which trap dirt particles throughout its volume. Once a cartridge reaches its holding capacity, it is disposed of and replaced by a new one.

Adsorption of Dissolved Organics and Chlorine

Activated carbon filters often found in pharmaceutical water purification systems are used to remove chlorine and many dissolved organic materials found in the incoming potable water. Physically, a carbon filter looks exactly like the multimedia filter: a vertical tank with a valve manifold next to it. The main difference is that the filter bed consists of activated carbon particles with a very high surface area. These can absorb and retain amazing amounts of organic contaminants and chlorine. The major disadvantage of carbon filters is that they may become a breeding ground for bacteria thriving in an environment without chlorine (which is typically adsorbed in the upper part of the bed) and with plenty of nutrients. Therefore carbon filters are usually periodically sanitized with hot water to contain microbial growth. The bed is also backwashed frequently to remove captured particles. However, activated carbon cannot be economically regenerated in the field; once it has reached its adsorption capacity (typically after 1–5 years), the bed is replaced with fresh carbon. It is recommended to use acid-washed activated carbon for water purification because the minerals resident in the charcoal may lead to leaching of the metal oxides, increasing the water hardness.^[2]

Ion Exchange

An ion exchange process is based on the ability of certain synthetic resins to selectively adsorb either cations or anions, and to release (exchange) other ions based on their relative activity. The water passes through a bed of resin beads in a vertical vessel (again, looking very similar to a multimedia filter), where such exchange takes place. Once all the active sites on the resin bed are filled with the new ions, the resin needs to be regenerated by passing an appropriate chemical solution through the bed.

The most common type of ion exchange system is a water softener. Its main function is to remove calcium and magnesium ions from hard water. These are the components that cause the formation of the hard-to-remove scale in tea kettles; they have a similar effect on boilers, distillation stills, and membrane filtration equipment. The polystyrene resin has a greater affinity for multivalent ions such as calcium and magnesium than for monovalent sodium. When the water passes through the bed, calcium and magnesium ions are captured and exchanged for the sodium adsorbed on the fresh resin. Once the resin is exhausted, it is regenerated by a 10% solution of sodium chloride. The high concentration of sodium ions in such a solution shifts the equilibrium of the adsorption-desorption process, resulting in the displacement of captured multivalent ions with sodium ions. The regeneration cycle can be repeated many times, making softener resin last for years. Softening is a very simple and inexpensive process requiring only salt for resin regeneration, and it is widely used not only in high-purity water systems but also in many utility water systems.

A similar process also takes place in ion exchange deionizers, designed to remove practically all foreign ions from water. Deionizers use two types of resin: one exchanges positively charged ions (cations) such as sodium, calcium, and magnesium with hydrogen ions (H^+); another exchanges negative ions (anions) such as chloride, sulfate, and bicarbonate with hydroxide (OH^-). Although the ion exchange process can produce very-

high-quality water, its major drawback is the type of chemicals required for resin regeneration: cation resins are regenerated by strong acid, and anion resins are regenerated by strong base solutions. Another drawback important for the pharmaceutical water systems is the fact that ion exchange resins can become a breeding ground for microorganisms. For smaller systems, it is common to use service-type ion exchange units, where the vessel with exhausted resin is taken offsite for regeneration, whereas larger systems have to be regenerated on site, resulting in the need to handle concentrated acids and bases and to neutralize waste solutions. A relatively new process gaining popularity in the field is the continuous deionization system, which represents a combination of ion exchange and membrane separation technologies. It uses electrical current to continuously regenerate the ion exchange resin simultaneously with the water treatment process, eliminating the need to handle strong chemicals.

Membrane Filtration

Unlike depth filters where particles are captured throughout the filter volume, membrane filters are surface-type filters: they stop particles larger than the pore size right at the upstream surface of the polymeric membrane. Naturally, such filters have very limited holding capacity: once most of the surface holes are plugged with a single particle each, the filtration process stops. To overcome this inherent limitation, engineers invented a process called “crossflow” or “tangential flow” filtration. In such a system (Fig. 1), fluid moves at high velocity parallel to the membrane, with only a small fraction of the feed flow penetrating through it because of a pressure differential. The particles or molecules that could not penetrate through the membrane are swept by the parallel flow and exit the system in a stream called “concentrate” because it contains a higher concentration of particles than the feed stream. The stream penetrating through the membrane is called “permeate.” Because of the “sweeping” action of the crossflow stream, membrane holes do

Fig. 1 Tangential flow filtration.

not plug up and such systems can function for a long time between cleanings. Depending on the pore size, membrane filtration processes are called microfiltration, ultrafiltration, and reverse osmosis (RO).

Microfilters use membranes with pores in the 0.1–1 μm range. They can filter out particles of dust, activated carbon, and ion exchange resin fines, and most microorganisms. Microfilters require low differential pressures (5–20 psi) and are available both as normal flow (“dead end”) and crossflow configurations. In pharmaceutical water purification systems, they are often used as disposable cartridge filters after activated carbon filters, softeners, and ion exchange beds.

Ultrafilters use membranes that reject not only solid particles but also dissolved matter with high molecular weight. The “molecular weight cutoff” point of such membranes varies in the range of 10,000–100,000 Da. They can remove bacteria, endotoxins, colloidal contaminants, and large organic molecules. Ultrafilters typically require differential pressure between 10 and 50 psi, and they are also available in both normal and crossflow configurations. In water purification systems, ultrafilters are sometimes used as a polishing step after ion exchange units.

Reverse osmosis is a filtration process using a membrane with the pore size in the range of 1–10 Å. Such membranes reject not only most organic compounds, bacteria, and viruses, but also 90–99% of all ions. Because of the extremely small pore size, RO systems operate at high differential pressures—typically from 100 to 500 psi. Practically all commercial RO systems are

designed in the crossflow configuration. The most common physical membrane configuration for RO systems uses spiral-wound elements (Fig. 2) placed into horizontal pressure vessels (essentially pipes). In the production of the pharmaceutical Purified Water, it is very common to use double-pass RO systems with two filtration stages connected in series. Such systems can easily produce water meeting the requirements for USP Purified Water and even WFI.^[3] However, European regulations do not allow RO to be used as a final treatment step for the production of WFI. This also affects U.S. facilities as the common practice in the United States is to build facilities compliant with both U.S. and European regulations. In the last 10–15 years, RO has become the most common way to produce pharmaceutical Purified Water—either as a final treatment step, or as pretreatment for the distillation stills.

Distillation

Distillation is a process that involves the evaporation of water and then the condensation of the resulting steam. Most dissolved contaminants do not evaporate at the temperature of boiling water, and therefore do not pass into the steam and condensate streams. To improve energy efficiency, distillation is usually conducted in multiple-effect stills designed to recover most of the energy spent on evaporating water. Distillation, while expensive, allows the removal of almost all of the organic and inorganic impurities and achieves very-high-quality water. It is also considered the safest way to avoid microbial

Fig. 2 Spiral-wound membrane element. (Courtesy of Osmonics Inc.)

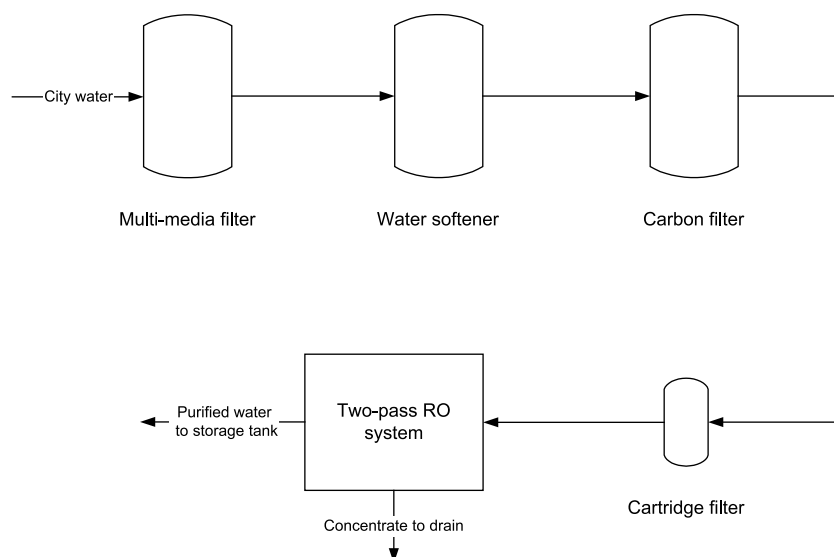

Fig. 3 Pharmaceutical water purification system.

and endotoxin contamination. That is why distillation remains the dominant method of producing WFI. Feed water to the distillation stills is often pretreated with RO and/or other methods to reduce scaling and to increase distillate quality.

One of the possible configurations for the pharmaceutical water purification system is shown in Fig. 3. The first three stages in that system (multimedia filtration, softening, and carbon filtration) are considered pretreatment steps for the RO unit that conducts final purification. The cartridge filter shown before the RO is provided to protect the membranes from the fine carbon particles. There are many variations of the treatment systems: sometimes carbon filter is placed before a softener, sometimes it is eliminated completely, and chlorine removal is accomplished by adding reducing chemicals such as sodium sulfite; often ultraviolet (UV) lights are added to improve microbial control and/or to reduce TOC levels, etc. The systems designed to produce WFI most often include distillation still as a final treatment step.

STORAGE AND DISTRIBUTION SYSTEMS FOR PHARMACEUTICAL WATER

Further discussion assumes that water leaving the purification system and entering the storage tank meets all of the above requirements either for USP Purified Water or WFI. The goal when designing and operating the storage and distribution system is to keep the water at these purity levels, preventing any of the four parameters listed above

from exceeding allowable limits during storage. In particular, the engineers and operators have to ensure that:

- Water is protected against ionic and organic contamination (that would lead to an increase in the conductivity and TOC respectively).
- The system is protected against physical entry of foreign particles and microorganisms.
- Microbial growth is prevented or minimized.

Before moving on to the description of the typical storage and distribution systems and their components, it is beneficial to say a few words about the issue of the microbial growth that presents probably the biggest challenge and causes most concerns among engineers and operating personnel.

Microorganisms are ubiquitous; they can be found in a very wide variety of environments. High-purity water systems are no exception. Although such water contains very few nutrients necessary to sustain life, some types of bacteria developed skills that allow them not only to survive but also to multiply in such waters. They do it for the most part by attaching themselves to the pipe and other system's surfaces and by creating a thin film containing microorganisms, organic and inorganic nutrients (obtained partially from the water and partially from the dead bacteria), and products of bacterial metabolism and decay.^[4-6] Such film, appropriately called biofilm, constitutes a niche environment that is very different from the bulk of the water system's volume, and may be reasonably comfortable for such bacteria. The majority of microorganisms capable of forming biofilms in the

purified water systems are classified as Gram-negative organisms in reference to their quality of not retaining a dye after staining (Cristian Gram was the inventor of the staining method). Such organisms have a tendency to shed lipopolysaccharidic materials from the cell membranes that constitute endotoxins, both during their normal growth and after the cell's destruction. That is why elimination of the Gram-negative microorganisms from the water systems is one of the primary goals. That also explains why test samples taken from the water system soon after sanitization sometimes show higher levels of endotoxins than those observed before: successful sanitization kills all or most of the bacteria in the biofilm, and pieces of their membranes are released in the bulk water stream where they can be detected as endotoxins. Another consequence of bacterial growth in biofilms that must be kept in mind is that results of microbial sampling of the water systems are only indirectly correlated with the actual situation. First, the sample is usually taken from the bulk liquid stream whereas most bacteria reside on the pipe and equipment surfaces. Second, the testing techniques, including the type of growth media used to cultivate the sample before counting colonies, can have a great impact on the test results. Therefore it is no accident that USP does not specify an allowable concentration of microorganisms in the water samples as a pass-fail criteria similar to conductivity or TOC, but only as a helpful indirect indicator that shall be used as an alert or action limit in the efforts to maintain microbial control.

It is important to point out that a small number of microorganisms surviving in the purified water system do not necessarily affect the water quality. Because of the lack of nutrients and other unfavorable conditions, the microbial growth in such waters is very slow. That provides operators with an option to maintain such systems in the state of microbial control by sanitizing them periodically rather than continuously, as long as the frequency is high enough to keep the bacterial counts at acceptable low levels.^[7,8]

Let us consider some of the engineering practices used to achieve the above mentioned goals. For a more detailed description, refer to the ISPE Baseline Pharmaceutical Engineering Guides^[9] recently developed to help industry professionals in designing and operating purified water systems.

Overall System Schematics

One of the typical flow diagrams for the pharmaceutical water storage and distribution system is shown in Fig. 4. The system includes a vertical storage tank, circulation pump, sanitary heat exchanger, and piping designed in the form of complete loop with point-of-use valves located at the minimum distance to the loop. The pump continuously circulates the water from the tank via distribution piping and back to the tank. The water temperature in the system is maintained at 65–85°C to maintain microbial control; any organisms that found their way into the system would be killed or at least prevented from multiplying at such

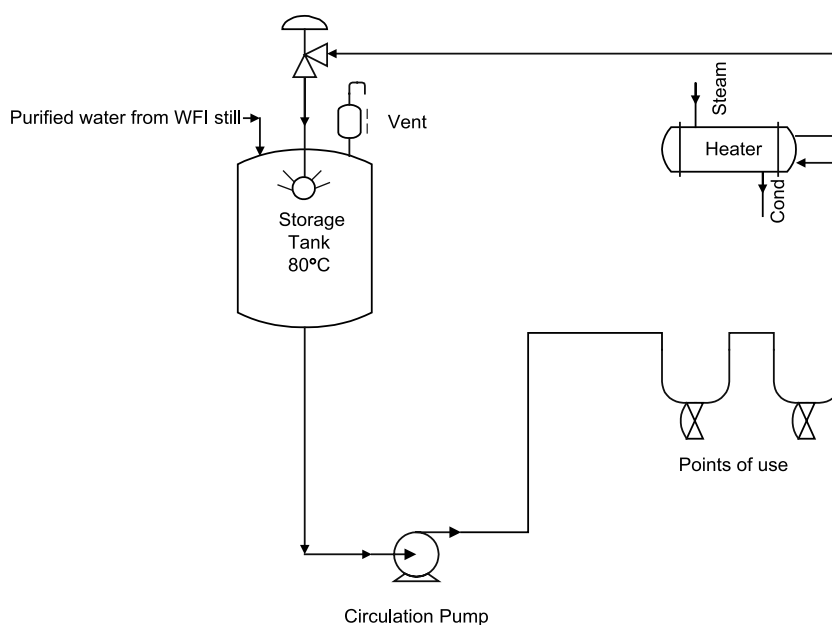

Fig. 4 Purified water storage and distribution system.

temperatures. The heat exchanger is used to compensate for the heat losses occurring in the piping system. The water is returned to the tank via one or more spray balls, thus providing continuous flushing of the tank's top head and upper walls, and keeping them at the high temperature. The entire system (tank, piping, and other components) is insulated for heat conservation. To minimize the "dead legs" at the points of use, it is common to design the loop with U-shaped sections located at each such point, in essence bringing the main header from the ceiling space to a convenient working level where a point-of-use valve would be easily accessible. That adds a lot of elbows and associated pressure drop to the system. In cases where the point-of-use valve is automated, this can sometimes be avoided by locating the valve at the header, away from the actual point of use. In such case, the valve only needs to be accessible for maintenance, but sanitization of the branch line may have to be addressed.

The storage tank is usually equipped with a sterilizing-grade (0.2 μm) hydrophobic vent filter, and sometimes also with a nitrogen blanketing system, to prevent the introduction of particles and organisms during normal

inbreathing. The additional benefits of the nitrogen blanket are the creation of oxygen-free atmosphere in the storage tank's upper space (better for microbial control and corrosion protection), and the avoidance of the slight vacuum conditions during the inbreathing via vent filter. The vent filter on the storage tank is often heat-traced to stay hot, both for microbial control and for prevention of moisture condensation.

The water circulation pump must be of sanitary design and may be equipped either with a single or a double mechanical seal. In the latter case, the purified water from the pump's discharge is used as a seal flush fluid (Fig. 5). If a spare circulation pump is installed for reliability, it is important to ensure that it does not constitute a long "dead leg." This can be avoided either by valving it off and draining it free of water when not in use, or by allowing a small flow of hot water to constantly circulate through the spare pump.

The circulation flow rate is usually selected based not only on the anticipated water usage rates, but also on the requirement to maintain certain minimum velocity (typically 5 ft/sec) during periods of no usage. The minimum

Fig. 5 Double mechanical seal with purified water flush arrangement. (Courtesy of Fristam Pumps Inc.) (Go to www.dekker.com to view this figure in color.)

velocity requirement comes from a widely held belief that 5 ft/sec is necessary to create a turbulent flow and that such flow prevents the accumulation of the biofilm by mechanical shear forces. However, this notion is not supported by experimental results or analysis of the fluid dynamics.^[10,11] First, the flow becomes turbulent at velocities well below 5 ft/sec. Second, even with the turbulent flow, there is always a thin film of liquid adjacent to the piping wall that exhibits laminar flow. The thickness of this film, although dependent on the velocity, is certainly much higher than the size of typical bacteria. However, it would be unfair to say that the circulation velocity does not matter. It shall be selected not only based on the pipeline hydraulics, but also considering its effect on maintaining required water temperature at the various points in the system, including any “dead legs.” The longer the “dead leg” is, the higher is degree of turbulence needed to keep it hot.

Although hot storage and distribution systems similar to the one shown in Fig. 4 above are excellent from the standpoint of microbial control, their main limitation is the fact that water is delivered to all users at the high (65–85°C) temperature. Very often, this is not acceptable for some or all users. Other disadvantages of the hot systems are the higher potential for corrosion of the construction materials, and personnel safety concerns related to the

high water temperature. Various design concepts have been developed to provide the users with purified water at required (usually ambient) temperature.^[12] Two of them are shown in Figs. 6 and 7. In the first case (Fig. 6), water is cooled directly at the point-of-use by a local cooler; in the second case (Fig. 7), a separate ambient temperature loop is created, where one central cooler serves the needs of multiple use points. During the periods of no water usage, the cooler in the system in Fig. 7 does almost nothing (just compensating for the heat gains from the pump). However, once a point-of-use valve is opened and ambient water starts flowing out of the loop, it is replaced by hot water from the storage tank. At this point, the cooler needs to be able to remove a lot of heat to keep the set loop temperature. That usually requires a very large sanitary heat exchanger and a lot of cooling water. From the practical prospective, it is often beneficial to install two exchangers in series: the first one uses cooling tower water to remove most of the heat, whereas the second (“trim cooler”) uses more expensive chilled water to bring the loop to required temperature (typically 20–25°C). It is important to point out that such system cannot be expected to maintain exact loop temperature at all times. Because of the control system delays inherent in its design, the purified water temperature will fluctuate by a few degrees every time a major use point valve opens or closes. This is

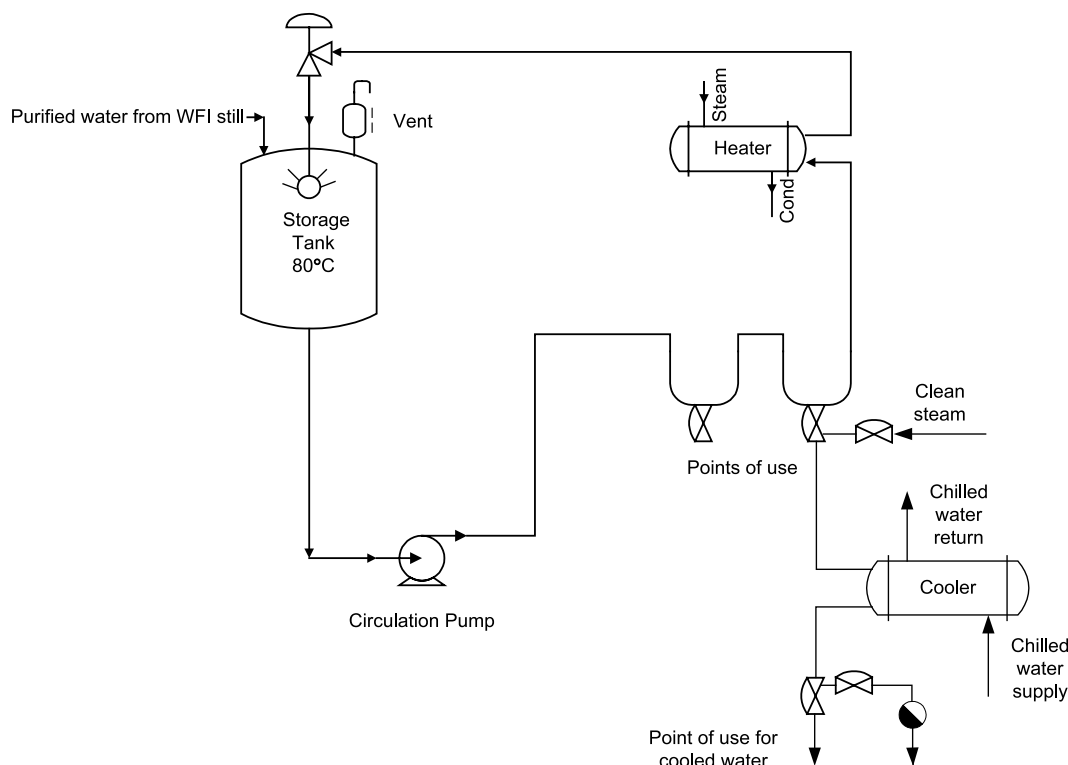

Fig. 6 Purified water storage and distribution system with point-of-use cooler.

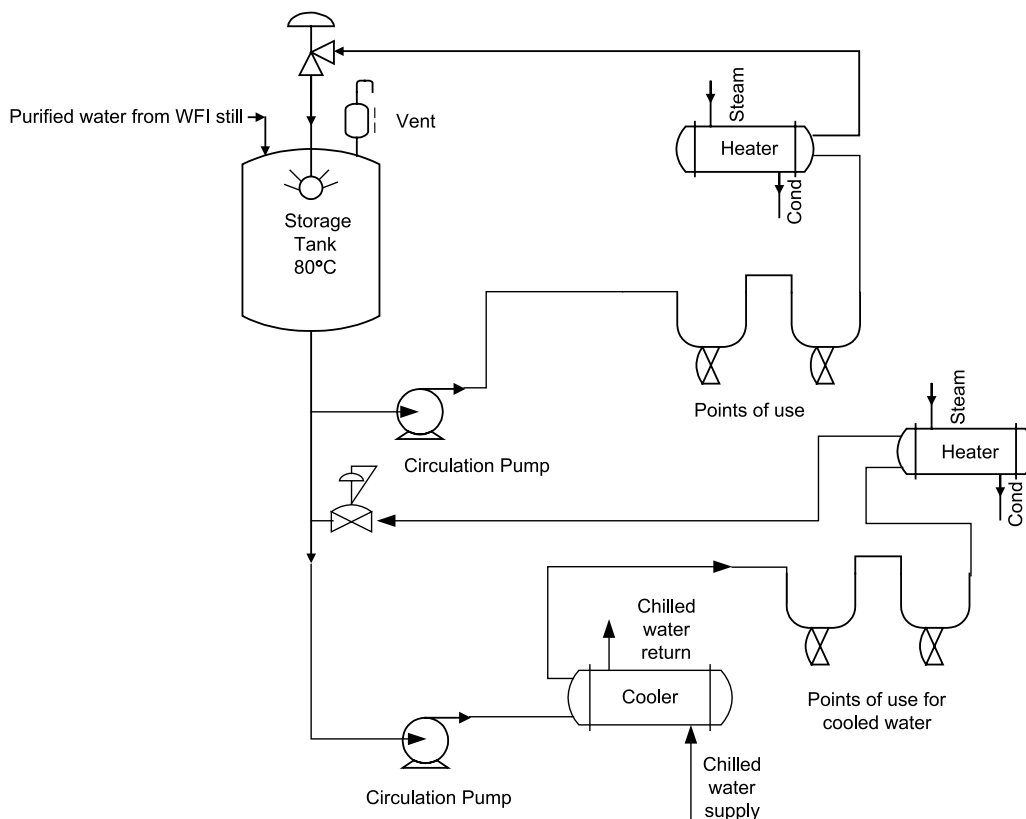

Fig. 7 Purified water storage and distribution system with ambient loop.

normally not a problem, especially in the applications involving filling the water into a process vessel. The heater in the ambient loop (Fig. 7) is provided for periodical loop sanitization; the steam supply is shut off at all other times.

A third approach is to use the system similar to the one shown in Fig. 4, but to keep the water in the storage tank and in the circulation loop at ambient temperature most of the time (this requires an extra heat exchanger with cooling water on the shell side). To achieve microbial control, such system (or any system that includes ambient loop) needs to be periodically sanitized by heating up its contents to about 80°C and holding the temperature for at least 1 hr. The sanitization frequency can vary from once a day to once a week or less: the lower the frequency is, the more attention to the studies proving the effectiveness of the microbial control shall be expected.

An alternative approach to microbial control in the ambient systems is to use ozone as a sanitizing agent. In such case, ozone gas (generated onsite from compressed air or oxygen) is continuously injected into the purified water storage tank. An UV light fixture is installed at the outlet of the circulation pump to decompose ozone in the water directed to the users during normal operation. Periodically, this UV light is shut off for 30 min to 1 hr,

allowing ozonated water to circulate through the distribution piping, thereby achieving its sanitization.

In larger systems, it often becomes impractical to run one large-diameter piping loop to all use points; in such cases, various multiloop arrangements may be employed.^[13]

The selection of a particular system design depends on many factors: number of use points requiring ambient and hot water, flow rates and frequency of usage, availability of capital, etc.^[14]

Materials of Construction

Storage tank, piping, pumps, and other components of the system in contact with purified water should be made out of materials that are chemically resistant to such water and which will not introduce metal ions or other contaminants. The most common material used in the pharmaceutical industry is 316L stainless steel. The suffix “L” in the grade designation stands for “low carbon,” which is important for the components that need to be welded because carbon molecules tend to diffuse to the surface during welding, making weld areas susceptible to corrosion. The piping systems for purified water are usually

constructed of the sanitary tubing. This product has tighter dimensional tolerances than piping, and is available with the wide range of surface finishes, up to the mirrorlike surfaces achieved by the combination of mechanical polishing and electropolishing. It is common to use the tubing polished to 25–30 μm . roughness average (RA) or better.^[15]

The tubing and other components (valves, elbows, tees, etc.) are welded for the most part by the automatic orbital welding machines. Such machines work by creating an electrical arc between the weld electrode and the tubing pieces, melting the ends of the tubes being joined. Unlike conventional welding, this technique creates a very smooth weld containing only the materials from the joined pieces and no metal from the welding electrode. To avoid excessive oxidation of the weld area, it has to be purged with inert gas such as argon during the procedure. In addition to reducing the manual labor, the automatic welding machines help in maintaining a consistent quality of all welds, as well as in documenting parameters (electrical current, electrode speed, purge flow, etc.) affecting such quality. Where automatic welding is not feasible (such as, for example, in the fabrication of zero-static valves), manual welding is allowed; however, it is recommended that it be conducted in the controlled shop environment rather than at the construction site. Welds in sanitary piping are often inspected by borescoping.

To improve the corrosion resistance of the stainless steel components, particularly in the weld-affected areas, it is a common practice to passivate the product contact surfaces of installed piping and equipment by circulating a solution of strong oxidant such as nitric or citric acid, or a chelating agent. Passivation removes free iron from the metal surface and creates a thin protective layer of chromium oxide. It is not uncommon to repeat the passivation treatment periodically (every few years) to restore the passive layer.

In the later years, some of the systems are designed with the plastic materials of construction instead of the stainless steel. The most common is polyvinylidene fluoride (PVDF); it is a partially fluorinated polymer that exhibits many desirable properties (mechanical strength and chemical resistance) approaching those of the fully fluorinated Teflon, but is less expensive and better suited for the installation in piping systems. Properly designed and supported PVDF piping can withstand hot water or even low-pressure steam sanitization, as well as periodical exposure to ozone. Although the PVDF tubing itself costs about as much as the stainless steel and requires continuous support in most cases, it offers advantages such as light weight, easier welding, less expensive valves and fittings, and no need for passivation. These benefits may result in overall installed cost savings compared to the stainless steel systems. Because of the concern about the

leaching of organic impurities from plastics, researchers and suppliers of the sanitary PVDF tubing conducted extensive studies proving that the amount of TOC leached from such tubing into water is very low and does not degrade the water quality.^[16,17] It is fair to say that whereas none of the construction materials can be considered ideal for the purified water systems, plastics such as PVDF emerge as strong competitors to the stainless steel.^[18]

Piping Design and Installation

While designing and installing the piping system for purified water, care shall be taken to avoid any areas

Fig. 8 Weir-style diaphragm valves: shutoff and point-of-use configurations. (Courtesy of ITT Industries.)

where water would remain stagnant (“dead legs”). Where branch connections are necessary, such as at the points of use, instrument ports, etc., the length of the “dead leg” is usually limited to a maximum of three pipe diameters of the branch line, as measured from the main line wall. The importance of this “rule of thumb” in this particular application is in the fact that while the piping system is being sanitized (either periodically or continuously), all parts of it, including the most remote areas, have to reach the required temperature, or, in case of chemical sanitization, be accessible for that chemical. In cases where long “dead legs” cannot be avoided (such as in some existing systems or in smaller new systems), microbial control can be achieved by flushing each of such legs with hot water or chemical solution as part of the sanitization procedure. The piping is usually sloped a minimum of 1/8 in/ft (or about 1:100) toward the nearest drain point to ensure complete drainage. Keep in mind that the thin-walled tubing used for the sanitary systems may sag

between the support points, which would create undrainable pools of liquid in the horizontal runs. Technically speaking, this sloping requirement is only important for the lines sanitized by steam (the condensate needs to drain freely to achieve even heating of all pipe surfaces), but it has become such a common practice that the author is not aware of any purified water systems in the pharmaceutical industry installed without slope. Most of the piping and other system elements are welded, and those components that may require disassembly (pumps, heat exchangers, instruments, etc.) are connected by sanitary joints such as Tri-Clamp, Swagelock TS, etc. The common feature of all such joints is that gasket fits flush to the tube wall, making the joint crevice-free. Diaphragm valves have become a de facto standard for purified water as well as for most other sanitary systems because of their cleanability, absence of crevices, and complete isolation of the wetted parts from the actuator mechanism. The two most widely used styles are weir and radial diaphragm valves, respectively. In addition to simple (one inlet, one outlet) valve configuration, several companies offer a wide variety of point-of-use and other specialty valves designed for the pharmaceutical and related industries in general, and for the purified water systems in particular (Figs. 8 and 9).

CONCLUSION

There are many types of purified water systems used in pharmaceutical facilities. Although most of them share common features, each system is custom-designed for a specific application. Developing a proper design requires a good understanding of system operation and careful attention to details. Simply following common “rules of thumb” does not necessarily guarantee a reliable system—no matter how much money is spent. On the other hand, with a good understanding, it is often possible to design, install, and validate a functional and reliable purified water system with less capital investment and lower operating costs.

WATER SORPTION OF DRUGS AND DOSAGE FORMS^a

Mark J. Kontny

Pharmacia, Kalamazoo, Michigan, U.S.A.

James J. Conners

Dura Pharmaceuticals, San Diego, California, U.S.A.

INTRODUCTION

The physical, chemical, and mechanical properties of pharmaceutical drugs and dosage forms are critically dependent on the presence of moisture. Pharmaceutical scientists can cite numerous examples of desirable and undesirable properties that result from varied levels of moisture associated with a particular solid or formulation consisting of mixtures of solids. Flow, compaction, caking, disintegration, dissolution, hardness, and chemical stability are just some of the properties influenced by moisture. Because water is present in bulk liquid form or as a vapor at some relative humidity in virtually all stages of solid manufacture (active ingredient and excipients), storage, processing into formulations, and final product packaging, a fundamental understanding of the role of water in affecting solid properties (and vice versa) is necessary.

Although the properties of individual solids and the performance of solid dosage forms are dependent on moisture, characterization of the underlying water–solid interaction is often nebulous. For example, many solids are described as “hygroscopic” without further reference to whether and how this relates to the rate and amount of moisture uptake as a function of relative humidity and temperature (1). To illustrate this ambiguity, consider that water-soluble, nonhydrating crystalline substances such as sodium chloride sorb very low levels of moisture (e.g., less than 0.1%) below their critical relative humidities, where the solid actually dissolves in the sorbed moisture. On the other hand, some typical excipient materials used in solid dosage forms, such as starches, celluloses, and gelatin capsules, sorb significant quantities of moisture (e.g., 25–50%), and even though they do not dissolve, they do undergo significant morphological change at high relative humidities (i.e., swelling). Moisture uptake rate

for a material depends on both the relative humidity of the environment and the time-dependent moisture content of the solid. For situations in which the environmental relative humidity is significantly different from the relative humidity at which the excipient (gelatin, for example) was previously equilibrated, the initial moisture uptake/loss rate will be significant, but it will approach zero over time. On the other hand, a water-soluble, nonhydrating crystalline substance such as sodium chloride will have a very low moisture uptake/loss rate that will decrease to zero if the environmental relative humidity is kept below its critical relative humidity. However, the uptake rate will be relatively large and continuous, until all the solid has dissolved, if the relative humidity is above the critical value. Obviously, very different mechanisms of water sorption/desorption occur for the different samples. In this light, describing sodium chloride and/or starch as “hygroscopic” offers very little toward understanding the water–solid interactions that might affect their physico-chemical properties. These examples illustrate the need to understand the underlying mechanism(s) of uptake for a particular solid. In this regard, therefore, addressing the following questions provides a basis for studying the various mechanisms of water–solid interaction:

1. How much water is present and what is the corresponding water activity (approximated by relative pressure or percent relative humidity/100)?
2. What are the kinetics of moisture uptake or loss, and is the rate constant or changing over time?
3. Where is the water located (i.e., adsorbed to the external surface of crystals, absorbed into crystals as specific or nonspecific water of hydration, absorbed into amorphous regions, condensed into pores, etc.)?
4. What is the state of the moisture associated with the solid (i.e., bulk water, water of hydration, physisorbed water, etc.)?
5. What form of the solid is present (i.e., particle size and morphology, polymorphic species, degree of crystallinity, state of hydration) and is this form

^aThis work was taken in part from a chapter entitled “Sorption of Water by Solids,” in *Physical Characterization of Pharmaceutical Solids*, H. Brittain, Ed., Marcel Dekker, Inc.: New York, 1995.

thermodynamically stable over the temperature and relative humidity range that the solid is expected to encounter?

It is the objective of this chapter to highlight the various mechanisms whereby water can interact with solid substances, present methodologies that can be used to obtain the necessary data, and then discuss moisture uptake for nonhydrating and hydrating crystalline solids below and above their critical relative humidities for amorphous solids and for pharmaceutically processed substances. Finally transfer of moisture from one substance to another will be discussed.

THE WATER SORPTION ISOTHERM

The most fundamental manner of demonstrating the relationship between sorbed water vapor and a solid is the water sorption–desorption isotherm. The water sorption–desorption isotherm describes the relationship between the equilibrium amount of water vapor sorbed to a solid (usually expressed as amount per unit mass or per unit surface area of solid) and the thermodynamic quantity, water activity (a_w), at constant temperature and pressure. At equilibrium the chemical potential of water sorbed to the solid must equal the chemical potential of water in the vapor phase. Water activity in the vapor phase is related to chemical potential by

$$\mu = \mu^0 + RT \ln a_w \quad (1)$$

where μ is the chemical potential of water in the system at equilibrium, μ^0 is the standard chemical potential of water at a specific reference temperature and pressure, R is the gas constant, and T is the absolute temperature. Lewis et al. (2) defined the relative activity of any pure substance or component (such as water) as a ratio of fugacities:

$$a_w = \frac{f_w}{f_w^0} \quad (2)$$

where f_w is the fugacity of water in the system at equilibrium and f_w^0 is the fugacity of pure water at a standard temperature and pressure. For all practical purposes, the fugacity (or “escaping tendency”) of water vapor can be approximated by the water vapor pressure in the system. This assumption is valid as long as the water vapor behaves as an ideal gas. For the water vapor pressure range of relevance for pharmaceutical systems at temperatures less than 50°C, this approximation is excellent (<0.2% relative error) (3). Thus, the relative

pressure of water vapor, P/P^0 , is usually employed as an estimate of the relative water activity in the system:

$$a_w = \frac{P}{P^0} \quad (3)$$

where P is the water vapor pressure in the system and P^0 is the vapor pressure above pure water at the temperature of interest. Relative humidity (RH) is defined as the relative pressure expressed on a percentage basis:

$$\text{RH} = 100 \frac{P}{P^0} \quad (4)$$

The sorption branch of the isotherm is obtained experimentally by measuring the equilibrium amount of water sorbed to a solid at known relative pressure, beginning with a known mass of absolutely dry solid and then progressively increasing the relative pressure in the system. Drying the solid sample under heat, possibly using vacuum to facilitate the removal of desorbed water vapor, is usually necessary to eliminate residual moisture. One must be aware, however, of the effects of such conditions on the chemical and physical stability of the solid. The desorption portion of the isotherm is obtained by progressively decreasing the relative pressure in the system from a relative pressure of approximately unity, again monitoring the equilibrium amount of moisture sorbed at each relative pressure. Remember that the moisture sorption isotherm is an equilibrium measurement of the interaction of water with a solid. In theory, information regarding the kinetics of moisture uptake is not explicitly derived from this experiment. This distinction is an important one that will be explored in more depth later.

Generation of water sorption–desorption isotherms for a particular solid can lend considerable insight into the nature of the water–solid interaction, as well as the surface characteristics of the solid. This information is readily obtained from the amount of moisture sorbed at lower relative humidities in comparison with the specific surface area of the sample, from the general shape of the isotherm, from whether or not water uptake is a completely reversible process (i.e., whether hysteresis is observed between sorption and desorption), and from the shape of the hysteresis loop if it is present. With knowledge of the aforementioned, one can usually obtain an indication of the mechanism of moisture sorption for the material of interest. For example, a material that exhibits sorption at lower relative humidities in much greater amounts than one might expect based on the specific surface area of the sample, and that exhibits hysteresis over the complete

range of relative humidities, is most likely absorbing water into its internal structure. On the other hand, a material exhibiting a closed hysteresis loop over the higher relative humidity range while sorbing moisture over the lower relative humidity range similar to what might be expected based on its specific surface area, is probably quite porous in nature and is most likely sorbing water via capillary condensation over the higher relative humidity range.

MODELS DESCRIBING VAPOR ADSORPTION

Brunauer, Emmett, and Teller Equation

The model most commonly referred to in the literature describing vapor adsorption onto solid surfaces was put forth in 1938 by Brunauer, Emmett, and Teller (4). The so-called BET model was originally derived using kinetic arguments in a manner very similar to those used by Langmuir (5). The BET model has since also been derived using statistical mechanics (6–8). The BET model assumes that vapor molecules, behaving as an ideal gas, exist in a state of equilibrium with a solid that consists of identical, homogeneous adsorption sites. The first vapor molecule adsorbed to an adsorption site on the solid is proposed to be bound, whereas molecules adsorbing beyond the first layer are assumed to have the properties of the bulk liquid. Furthermore, adsorption is proposed to occur such that the adsorbed molecules do not interact laterally. The linear form of the BET equation is

$$\frac{1}{W \left[\frac{P^0}{P-1} \right]} = \frac{(C_b - 1) * \frac{P}{P^0}}{W_m C_b} + \frac{1}{W_m C_b} \quad (5)$$

where W is the mass of vapor adsorbed per gram of solid at a particular relative pressure, P/P^0 ; W_m is the theoretical quantity of vapor adsorbed when each adsorption site has one vapor molecule adsorbed to it; and

$$C_b = k \exp \left(\frac{H_1 - H_L}{RT} \right) \quad (6)$$

where H_1 is the heat of adsorption of the first vapor molecule adsorbed to a site, H_L is the heat of condensation of the bulk adsorbate, R is the universal gas constant, T is the absolute temperature, and k is a constant, usually assumed to be close to unity. The two BET constants, W_m and C_b , can easily be obtained from the linear plotting form of the BET equation given in Eq. 5. Plotting the quantity $1/[W(P^0/P - 1)]$ versus P/P^0 gives a slope equal

to $(C_b - 1)/W_m C_b$ and an intercept equal to $1/W_m C_b$. Algebraic manipulation gives

$$W_m = \frac{1}{\text{slope} + \text{intercept}} \quad (7)$$

and

$$C_b = 1 + \frac{\text{slope}}{\text{intercept}} \quad (8)$$

In general, the BET equation fits adsorption data quite well over the relative pressure range 0.05–0.35, but predicts considerably more adsorption at higher relative pressures than is experimentally observed. This is consistent with an assumption built into the BET derivation that an infinite number of layers are adsorbed at a relative pressure of unity. Application of the BET equation to nonpolar gas adsorption results is carried out quite frequently to obtain estimates of the specific surface area of solid samples. By assuming a cross-sectional area for the adsorbate molecule, one can use W_m to calculate specific surface area by the following relationship:

$$S = \frac{W_m X N_{av}}{M \Sigma} \quad (9)$$

where S is the specific surface area in m^2/g ; W_m is the mass of adsorbate adsorbed at monolayer coverage; X is the cross-sectional area of an adsorbed adsorbate molecule (assumed to be 19.5 \AA^2 for krypton, 16.2 \AA^2 for nitrogen, 12.5 \AA^2 for water (9, 10)); N_{av} is Avogadro's number; M is the molecular weight of adsorbate; and Σ is the mass of the sample. Obviously, calculating surface areas from moisture uptake data that does not lead to monolayer coverage at W_m [either incomplete coverage (see the section on "Water Sorption onto Nonhydrates" below) or absorption into the solid (see the section on "The Meaning of Specific Surface Areas Calculated from Water Absorption Studies")] will result in incorrect values that have no physical meaning. Therefore, comparison of the surface area measured by nonpolar gas adsorption to that calculated from a moisture sorption isotherm can lend insight into the fundamental interactions between the water and the solid. This will be explored in some depth later.

Guggenheim and deBoer Equation

Many attempts to modify the BET adsorption theory have been made since its original derivation. Its simplicity and ability to fit adsorption data extremely well at lower relative pressures, however, have made it the model of choice for estimating surface areas from nonpolar gas

adsorption. Most modifications of the BET model, developed to analyze data over the entire range of relative pressures, usually add at least one fitting parameter to the equation. This makes computer fitting a necessity, because only two measurable parameters, W and P/P^0 , are available. From a modeling perspective, additional fitting parameters of unknown or undefined physical meaning that arise from such approaches are often a deterrent to the use of multiparameter models because of the consequent difficulty in interpreting results. In this regard, therefore, only a single modification of the BET model, which has been shown to extend the relative pressure range over which vapor adsorption data can be fit, will be considered here. This extension of the BET model, independently derived by Guggenheim (11) and deBoer (12), accounts for the adsorption of an intermediate state of vapor between the tightly bound first molecule adsorbing to an adsorption site and the condensed molecules adsorbed at very high relative pressures. Molecules adsorbed in the intermediate range can be considered to interact with the solid, but the interaction is assumed to be considerably less than that of the first molecule sorbed at an adsorption site. Obviously, this addition of a "third state" of interaction is an approximation. In all likelihood, there is a continuum of interaction states. However, from a computational point of view, the existence of three or more states is indistinguishable. The equation for the three-state interaction model is given as

$$W = \frac{W_m C_G K \frac{P}{P^0}}{\left[1 - K \frac{P}{P^0}\right] \left[1 - K \frac{P}{P^0} + C_G K \frac{P}{P^0}\right]} \quad (10)$$

where P , P^0 , H_L , W , and W_m are identical to the parameters used in the BET equation, and

$$K = B \exp\left(\frac{H_L - H_m}{RT}\right) \quad (11)$$

where B is a constant and H_m is the heat of adsorption of vapor adsorbed in the intermediate layer. The constant C_G is defined as

$$C_G = D \exp(H_1 - H_m RT) \quad (12)$$

where D is a constant, H_1 is the heat of adsorption of the first molecule adsorbed at a site, and H_m is the heat of adsorption of the intermediately bound molecule.

Water Vapor Absorption by Amorphous Solids

The process of water vapor interaction with amorphous solids has been likened to the production of a solid solution in which the water is dissolved in the solid matrix. As more

water is absorbed, the fundamental properties of this solid matrix (e.g., viscosity) can undergo significant change that can then result in visually apparent changes in physical properties (e.g., collapse, recrystallization) (13–17). This will be discussed in further detail later.

Although water vapor is absorbed into amorphous solids and not simply adsorbed on the surface, it still has been found that such sorption isotherms can be fit to the BET equation up to a P/P^0 of about 0.40 as with vapor adsorption, and over the entire range of P/P^0 using its extension, Eq. 10. Because this was first reported by Anderson (18) to be the case for water absorption, Eq. 10, when applied to water vapor sorption, is often called the GAB equation for Guggenheim, Anderson, and deBoer (19). Because the theoretical process for the derivation of the original equation does not translate directly to the absorption process, which involves dissolution of water in the amorphous solid, the significance of fit to the GAB equation is somewhat limited. It is, however, a very useful equation because it does allow one to describe the entire isotherm and to draw out some useful parameters (to be discussed in what follows).

Since water vapor dissolves in the solid during absorption, several models based on solution theory, proposing that the sorbate is taken up into the solid as a solid solution, have been derived and used to describe water sorption on polymers [e.g., Flory-Huggins (20), Hallwood-Horrobin (21)]. More recently, Vrentas et al. (22, 23) developed a solution-based model that accounts for the plasticizing effect of water on a polymer that has been shown to describe the entire moisture uptake isotherm for the polymer (24). While these sorption theories and the many modifications of the BET adsorption model are based on meaningful physicochemical principles, further work is still required to elucidate the molecular mechanisms underlying moisture uptake into polymeric systems. From this perspective, other models based on entirely different theoretical concepts will not be considered further in this chapter. For further reference, the reader is directed to several excellent literature reviews of the many sorption theories that have been proposed (25, 26).

Capillary Condensation

Vapor sorption onto porous solids differs from vapor uptake onto the surfaces of flat materials in that a vapor (in this case, water) will condense to a liquid in a pore structure at a vapor pressure, P_r , below the vapor pressure, P^0 , where condensation occurs on flat surfaces. This is generally attributed to the increased attractive forces

between adsorbate molecules that occur as surfaces become highly curved, such as in a pore or capillary. This phenomenon is referred to as capillary condensation and is described by the Kelvin equation (27):

$$\ln\left(\frac{P_r}{P^0}\right) = -2\gamma V_m r RT \quad (13)$$

where γ is the surface tension of the adsorbed film (assumed equal to that of the bulk liquid), V_m is the molar volume of the liquid, r is the pore radius, R is the gas constant, and T is the temperature. The Kelvin equation has been shown to be applicable to pore radii as low as 5 nm for water adsorption onto mica (28, 29). As mentioned in the section on The Water Sorption Isotherm, capillary condensation will result in a closed hysteresis loop in the adsorption/desorption isotherm of a porous material. Calculating P_r/P^0 by assuming a surface tension of water of 72.8 ergs/cm² and a density of 0.998 g/cm³ at 293 K [this is an assumption for the purposes of this calculation as it has been shown that the density of water is lower in a pore than the bulk value (30)] shows that condensation is predicted at relative pressures of 0.998, 0.989, 0.898, and 0.340 for pore radii of 1000, 100, 10, and 1 nm, respectively. In this regard, it is clear that capillary condensation need only be considered for very small pore dimensions. In practical terms, one should be concerned about this mechanism of water uptake for microporous pharmaceutical powders that exhibit a relatively large specific surface area (i.e., >100 m²/g), as determined from nonpolar gas adsorption studies.

METHODOLOGY

Control of Relative Humidity

Maintenance of constant relative humidity environments is essential for studying water–solid interactions. There are primarily four techniques that are frequently employed to maintain constant relative humidity:

1. Colligative solutions.
2. Temperature modification of an aqueous solution.
3. Control of total pressure over the solid.
4. Mixing wet and dry air streams.

Saturated salt solutions and sulfuric acid solutions establish relative humidity by reducing the vapor pressure above an aqueous solution (a colligative effect). Saturated salt solutions at controlled temperature maintain a constant relative humidity as long as excess salt and bulk solution are present. As water is added or removed from the solution,

moisture from the headspace will either condense or evaporate (as appropriate), with subsequent dissolution or precipitation of salt to maintain the equilibrium vapor pressure. Because the degree of vapor pressure depression is dependent on the number of species in solution and, further, since the solubility of most salts is somewhat dependent on temperature, the relative humidity generated is also temperature dependent. Hence, use of the same salt at different temperatures can result in different relative humidities. Refs. 31–35 can be consulted for specific saturated salt solutions that result in defined relative humidities as a function of temperature. Because relative humidity is dependent on the number of dissolved species, it is essential that saturation be attained prior to beginning experimentation. In this regard, preparing the salt solutions several days before beginning a sorption study is recommended. Sulfuric acid solutions of varying concentration (35) are also used to establish relative humidity. Addition or removal of water from the solution by desorption or sorption of water to the solid, however, will alter the concentration of sulfuric acid (and water) in solution, and thus change the relative humidity of the headspace. This technique for controlling relative humidity in the headspace is practically more useful when small amounts of water are sorbed/desorbed from the solid.

Temperature modification of an aqueous solution can also be used to maintain constant relative humidity in the headspace (19). This technique maintains the solid at one temperature and an aqueous solution connected to the system at another temperature. Due to strong vapor pressure dependence on temperature, very tight temperature control of the aqueous solution and the solid are required to maintain constant relative humidity in the vicinity of the solid by this technique.

Control of the vapor pressure in the headspace over a solid can also be used to maintain a relative humidity over a solid. As shown in Eq. 4, the relative humidity is directly correlated to the partial pressure of water in the vapor phase. To utilize this technique for relative humidity control, the headspace above the sample must be completely evacuated prior to analysis. Pure water vapor can then be carefully admitted to the vapor phase. Because only water vapor is present, the pressure measured over the system is directly related to the relative humidity over the sample (36).

Mixing dry and water vapor saturated air in defined proportions also can be used to generate constant relative humidity. Control of flow rates and the water vapor content of the dry and saturated air are essential to ensure accurate, reproducible relative humidity production (37, 38).

Measurement of Relative Humidity

Measurement of relative humidity depends on the system used. Systems employing vacuum are usually evacuated prior to introduction of water vapor (36, 39). For cases in which a gas-forming reaction is not occurring, measurement of total pressure in the system can be used as a measure of water vapor pressure. Systems in which air is not evacuated require specific measurement of water vapor pressure. (For the latter type of system, caution should be taken to assure that the relative humidity source is in close proximity to the solid, since the diffusion of water vapor through air to the solid is required to maintain a constant relative humidity in the immediate vicinity of the solid.) A wide variety of pressure measuring instrumentation is commercially available with varying accuracy, precision, and cost.

Measurement of the Critical Relative Humidity, RH_0

The relative humidity at which a solid begins to deliquesce, RH_0 , can be determined in three ways: 1) directly, by measuring the relative humidity above a saturated solution of the substance; 2) by determining the relative humidity at which significant moisture uptake and simultaneous dissolution occurs, or; 3) indirectly, by measuring the steady state moisture uptake rate at relative humidities above RH_0 and then extrapolating to the relative humidity at which the moisture uptake rate is zero (1, 40, 41).

Although other techniques can be used to measure the relative humidity above a saturated solution, one relatively simple procedure is to evacuate the headspace (to remove air by vapor phase expansions) and then, with the vacuum pumps isolated and the saturated solution maintained at a constant temperature, to measure water vapor pressure. Water vapor pressure can then be converted to relative humidity by dividing by P^0 , the vapor pressure above pure water at the temperature of interest (42).

Measurement of Moisture Uptake (Kinetics of Deliquescence)

The rate of moisture uptake above RH_0 requires maintenance and measurement of a range of relative humidities, and the capability of measuring the moisture content of the solid over time. Use of a vacuum system can minimize vapor diffusion through the headspace, thus maintaining constant relative humidity in the vicinity of the sample. Also, because the most reliable estimate of the steady-state moisture uptake rate is when the integrity of the solid is intact and the film of sorbed moisture is thin

(and saturation most likely), it is advisable to determine the moisture uptake rate at early time periods. In this regard, it is also helpful to be able to view the solid during the experiment to verify that integrity is maintained and excess solid remains (41, 43).

Measurement of Equilibrium Moisture Sorption

Generation of water sorption/desorption isotherms in a controlled relative humidity environment can be carried out either gravimetrically or volumetrically. Gravimetric methods require

1. A dry sample weight,
2. Constant temperature of the sample,
3. Maintaining predetermined constant relative humidities in the headspace, and
4. Attaining and measuring an equilibrium weight of sorbed water vapor. Gravimetric measurement of moisture uptake can occur continuously or discontinuously. Continuous measurement usually involves placing a sample on a balance in a temperature- and relative humidity-controlled environment. Microbalances in closed systems have been used successfully for this purpose (37–39, 44), and commercial systems are now available that can accurately and precisely control relative humidity and simultaneously monitor sample weight.

Volumetric methods require

1. A dry sample weight,
2. Constant temperature of the sample,
3. Water vapor pressure measurement in a dosing volume and, later, in the headspace above the equilibrated sample, and
4. Measuring dead volumes of the individual chambers, including the sample chamber. In essence, volumetric methods equilibrate a known headspace dosing volume at a given (measured) water vapor pressure, followed by exposure of the pre-equilibrated sample to this water, with subsequent measurement of the water vapor pressure after equilibration. The mass of water sorbed, Δn (in moles), at the final pressure in the system, P_f , is obtained from the difference, ΔP , between P_f^{calc} , the calculated water vapor pressure at equilibrium, and P_f^{meas} , the final measured water vapor pressure:

$$\Delta n = \frac{\Delta PV}{RT} \quad (14)$$

where V is the final volume, R is the gas constant, and T is the absolute temperature (39).

WATER SORPTION BY CRYSTALLINE SOLIDS

General Model

Fig. 1 schematically describes the important steps in the uptake of water vapor by crystalline water-soluble solids. At low relative humidities, water is adsorbed to the surface of a nonhydrate-forming solid. As the relative humidity is increased, some tendency for multilayer sorption is expected. At some relative humidity (characteristic for a given substance), the solid will begin to dissolve in the sorbed film of water. A saturated solution of solute will most likely exist, and this will cause the vapor pressure over the sorbed film of water to be depressed relative to pure water and to be constant and equal to that above a saturated solution of the substance. This vapor pressure may be expressed as the critical relative humidity, RH_0 . If the relative humidity in the atmosphere is greater than that over the saturated solution (RH_0), water will spontaneously condense on the aqueous film. This will dilute the film allowing more solid to dissolve, which, in turn, will maintain the pressure gradient. The process of water vapor uptake will continue until all the solid has dissolved and further solution dilution has occurred. Only when the relative humidity above the solution is elevated to that of the atmosphere will this process terminate. This phenomenon is called deliquescence. Although hydrates undergo solid state transitions in transforming from the anhydrate to hydrate, as well as from one hydrate species to another, behavior similar to that previously described for nonhydrates is also noted at and above RH_0 for hydrates. In pharmaceutical systems, water-soluble species are frequently encountered in dosage forms. Thus, it is important to understand the conditions responsible for deliquescence and the molecular events occurring at relative humidities below the deliquescence point.

Fig. 1 Water vapor adsorption and deliquescence of a water-soluble solid at (a) atmospheric relative humidity, $RH_i < RH_0$; (b) $RH_i = RH_0$; (c) $RH_i > RH_0$.

Water Sorption onto Nonhydrates below RH_0

The sorption of water vapor onto nonhydrating crystalline solids below RH_0 will depend on the polarity of the surface(s) and will be proportional to surface area. For example, water exhibits little tendency to sorb to nonpolar solids like carbon or polytetrafluoroethylene (Teflon) (29), but it sorbs to a greater extent to more polar materials such as alkali halides (45–48) and organic salts like sodium salicylate (48). Because water is only sorbed to the external surface of these substances, relatively small amounts (i.e., typically less than 1 mg/g) of water are sorbed compared with hydrates and amorphous materials that absorb water into their internal structures.

Unfortunately, the literature is relatively sparse with examples showing the water uptake profile onto crystalline, nonhydrating substances below RH_0 . This is most likely due to the difficulty in accurately measuring the small amounts of water that are sorbed. Alkali halides are an exception, however, likely due to their well-characterized particle morphologies (45–48). Figure 2 shows a water uptake isotherm onto recrystallized sodium chloride (48). Note that the amount of water sorbed as a function of relative humidity is normalized to the specific surface area of the sample. Because water is sorbed only to the external surface of this material, this allows comparison of water uptake data from different lots of material, whereas plotting this data on a “per gram” basis would have little or no meaning. For the sodium chloride sample in Fig. 2 (specific surface area = $0.0875 \text{ m}^2/\text{g}$ from krypton adsorption studies), only $5 \times 10^{-4} \text{ g water/m}^2$ of sodium chloride is sorbed, even up to 70% relative humidity. Also, note the apparent step-like nature of the isotherm. From BET analysis of the sorption data at the lower relative humidities, a W_m value of $7.6 \times 10^{-5} \text{ g/m}^2$ is obtained. This value is only about 0.32 that of the predicted value for monolayer coverage assuming an area per water molecule of 12.5 \AA^2 . This suggests that it is quite meaningless to refer to the number of layers of sorbed water as multiples of W_m , except as a point of reference. Interestingly, the second step plateau in Fig. 2 occurs at about three times the moisture content corresponding to W_m , suggesting that for sodium chloride, the monolayer is actually completed during the second step of the isotherm. Isothermic heat of sorption results for sodium chloride from Barraclough and Hall (45) suggest that the heat of sorption of water up to W_m is invariant, whereas the heat of sorption decreases and becomes constant at about two times W_m . Considering the experimental error involved in obtaining W_m and the isosteric heats of sorption, this suggests that

Fig. 2 Water vapor sorption for recrystallized (□) and ground (*) sodium chloride at 20°C. (From Ref. 48.)

water is sorbed with a homogeneous binding energy up to W_m and then interacts to a lesser extent until the monolayer is complete.

As shown in Fig. 2 (48) and also in the work of Barraclough and Hall (45), moisture uptake onto sodium chloride as a function of relative humidity is reversible as long as RH_0 is not attained. This is evidence that actual dissolution of water-soluble crystalline substances does not occur below RH_0 . This is consistent with the thermodynamic rationale that dissolution below RH_0 would require a supersaturated solution (i.e., an increased number of species in solution would be necessary to induce dissolution at a relative humidity below that of the saturated solution, RH_0). In this regard, one should only need to consider the solid state properties of a purely crystalline material below RH_0 . As will be described, other considerations may be warranted for a substance that exists in multiple polymorphic forms or contains amorphous material.

Water Sorption onto Hydrates below RH_0

Many drugs and excipients (cephalexin monohydrate, quinidine sulfate dihydrate, ampicillin trihydrate, codeine sulfate trihydrate, morphine sulfate dihydrate, dicalcium phosphate trihydrate, raffinose pentahydrate, lactose monohydrate) utilize water as an integral part of their crystal structure. Solids that form specific crystal hydrates tend to sorb relatively small amounts of water to their external surface below a characteristic relative humidity, when initially dried to an anhydrous state. Below this characteristic relative humidity, these materials behave similarly to nonhydrates. Once the characteristic relative humidity is attained, addition of more water to the system will not result in a further increase in relative humidity. Rather, this water will be sorbed so that the anhydrate crystal will be converted to the hydrate. The strength of the water–solid interaction depends on the level of hydrogen bonding possible within the lattice (29, 49). In some hydrates (e.g., caffeine and theophylline) where hydrogen bonding is relatively weak, water molecules can aid in hydrate stabilization primarily due to their space-filling role (29, 49, 50).

Since water molecules occupy regular positions within the lattice of a hydrate with a specific stoichiometry (e.g., 1:1 monohydrate, 2:1 dihydrate, 5:1 pentahydrate) to the solid, relatively large quantities of water are sorbed. Fig. 3 shows a moisture uptake isotherm for ipratropium bromide (51). This substance undergoes an apparent hydration of the crystal between 63% and 75% relative humidity. Above 75% relative humidity, approximately 4.6% water is sorbed (theoretical monohydrate is 4.4%). Interestingly, as anhydrous ipratropium bromide is equilibrated for extended time periods (e.g., 2 and 5 months respectively, as shown in Fig. 3), hydration of the crystal appears to occur at 53% and 63% relative humidity. This example clearly shows that a time period of many months may be required to attain a reliable estimate of the equilibrium uptake at select relative humidities. Characteristic of many hydrates, ipratropium bromide exhibits significant hysteresis between the sorption and desorption isotherms. This is attributed to the degree of binding and the physical fit of water in the hydrated lattice.

Nonspecific hydration, or hydration of the lattice without a first-order phase transition, also must be considered. Cox et al. (52) reported the moisture uptake profile of cromolyn sodium, and the related effects on the physical properties of this substance. Although up to nine molecules of water per molecule of cromolyn sodium are sorbed into the crystalline lattice at 90% relative humidity,

Fig. 3 Water vapor sorption and desorption isotherms for ipratropium bromide at 20°C. (□) 2- month sorption results; (△) 5- month sorption results; (*) 2- and 5- month desorption results. (Note: All 2- month sorption results, except at 53% and 63% relative humidity, were verified at 5 months.)

the sorption profile does not show any sharp plateaus corresponding to fixed hydrates. Rather, the uptake profile exhibits a gradual increase in moisture content as relative humidity increases, which results in marked changes in X-ray diffraction patterns, density, and other physical properties. For this example, moisture uptake onto cromolyn sodium was correlated with expansion of the lattice in the *b* crystallographic direction, which was shown to be reversible on dehydration.

A thorough understanding of the hydration profile for a solid forming a crystal hydrate is important for several reasons. First, because an anhydrate and hydrate(s) are distinct thermodynamic species, they will have different physicochemical properties (e.g., solubility) that may affect dissolution or bioavailability. Second, a desired hydrate species can be formed and used (and retained) simply by controlling the established environmental conditions. Third, because significant quantities of water can be sorbed/liberated as a hydrate becomes hydrated/dehydrated, the physicochemical properties of the immediate system (including other nearby solids) can be markedly affected.

The Critical Relative Humidity, RH_0

Knowledge of RH_0 for each component in a formulation, and for the entire system, is extremely important for predicting relative humidities where gross physical changes of the system are expected due to dissolution of water-soluble components. The value of RH_0 , as a colligative property, is significantly influenced by the number of species in solution. As a rule of thumb, two general comments can be made. First, compounds exhibiting poor water solubility typically have RH_0 values well above 95% relative humidity. Second, as solubility increases, RH_0 decreases. Since nonidealities are introduced as solutions become more and more concentrated, it is not usually possible to use dilute solution models (e.g., Raoult's law) to predict the expected RH_0 for a solute of significant aqueous solubility. Hence, RH_0 should be measured for individual solids. Examples of RH_0 values for single component systems are shown in Table 1.

Values of RH_0 for mixtures, on the other hand, can be calculated from the RH_0 values of single components using an equation developed by Ross (54):

$$\frac{(RH_0)_{\text{mix}}}{100} = \left(\frac{(RH_0)_1}{100} \right) * \left(\frac{(RH_0)_2}{100} \right) * \left(\frac{(RH_0)_3}{100} \right) \cdot \cdot \cdot \quad (15)$$

Table 1 RH_0 values for single component systems at 25°C

where $(RH_0)_{\text{mix}}$ is the relative humidity above a saturated solution of the mixture and $(RH_0)_i$ represents the relative humidities of the individual saturated salt solutions. The Ross equation was derived assuming dilute solutions and negligible interaction between the components in solution. The results presented in Table 2 compare RH_0 values obtained by calculating RH_0 values for mixtures from the Ross equation and those obtained experimentally. Agreement is very good, especially considering the high levels of dissolved solute(s) that are attained (i.e., estimated as high as 50 molal for the choline bromide/tetrabutylammonium bromide system) (43).

The Kinetics of Deliquescence above RH_0

Initial work by Edgar and Swan (55), Adams and Merz (56), Prideaux (57), Morkowitz and Boryta (58), and Carstensen (1) suggested that the rate of moisture uptake onto water-soluble solids above RH_0 should depend on the difference between the partial pressure of water in the environment and that of the partial pressure of water above a saturated solution of the water-soluble substance, the temperature, the exposed surface area of the solid, the velocity of movement of the moist air, and a specific reaction constant that is characteristic of the individual solid.

Van Campen et al. (41) developed models describing the rate of moisture uptake above RH_0 that consider both the mass transport of water to the solid substance and the heat transfer away from the surface. For the special case of an environment consisting of pure water (i.e., initial vacuum conditions), the Van Campen et al. model is greatly simplified because vapor diffusion need not be considered. Here, only the rate at which heat is transported away from the surface is assumed to

be an important factor in limiting the sorption rate, W' . For this special case, an expression was derived to express the rate of moisture uptake solely as a function of RH_1 , the relative humidity of the environment, and RH_0 .

This model was shown to be applicable for describing moisture uptake kinetics (in vacuum) above RH_0 for single component systems of alkali halides, sugars, and choline salts (41). The model later was extended to consider the moisture uptake kinetics above RH_0 for multicomponent systems of these substances (43).

WATER SORPTION BY AMORPHOUS SOLIDS

Isotherm Analyses at Ambient Temperatures

The amount of moisture sorbed by amorphous solids is typically much greater than that sorbed by nonhydrating crystalline substances below their critical relative humidities. Typical substances of pharmaceutical interest in this class of solids include celluloses, starches, poly(vinylpyrrolidone), gelatin, and some lyophilized proteins. Although some of these substances exhibit partially crystalline character, they generally contain significant fractions of amorphous material and, thus, fall into this class of substances. A typical isotherm for microcrystalline cellulose is shown in Fig. 4. Note the significant amounts of water that are sorbed over the entire relative humidity range and that both the sorption and desorption isotherms are characterized by the classical sigmoidal shape often observed with the physical adsorption of gases. Also apparent is the hysteresis between the sorption and desorption portions of the isotherm (i.e., the amount of water associated with the solid is greater for the desorption isotherm than the sorption isotherm for a given relative

Fig. 4 Water vapor sorption (\square) and desorption (Δ) isotherms for microcrystalline cellulose at 20°C. Solid line: GAB fit to sorption data; Dashed line: GAB fit to desorption data.

pressure). This is typical for these types of materials and is generally attributed to either kinetic effects or to a change in the polymer chain conformation caused by plasticization effects of sorbed water (19, 59–62).

Fig. 4 also shows the excellent fit to the GAB equation (Eq. 10) of the sorption and desorption isotherms for microcrystalline cellulose. In this regard, this equation offers considerable practical utility in fitting isotherms for these types of materials over the entire relative humidity range, especially in contrast to the BET equation, which usually only fits uptake data up to about 40% relative humidity. As previously mentioned, however, this does not in itself confirm the validity of the GAB model for describing moisture sorption data on these materials. Rather, independent confirmation of the physical meaning is necessary.

Considerable physical insight has been gained into the primary binding mechanism of water onto starches and celluloses from isotherm analyses that yield values for W_m (Eqs. 5, 7, and 10). This is illustrated in Table 3, which gives W_m values for three types of starches (61). Table 3 shows that the values for W_m are quite constant despite

Table 3 W_m Values for various starches obtained from BET analysis of moisture uptake isotherms

Starch	W_m (g/g)	Reference
Corn	0.095 ^a	(39)
Corn	0.083	(63)
Potato	0.085	(19)
Wheat	0.080	(19)

^aThis value is taken from the desorption isotherm. Others are from sorption isotherms.

(From Ref. 61.)

significant morphological differences between the various starches. One value of W_m , taken from a fit of desorption data, appears to be slightly higher than values obtained from sorption data. This might be expected if the availability of primary sorption sites had been increased by previous exposure to elevated relative humidities, with subsequent increased levels of water sorption. As shown by Van den Berg et al. (19, 59, 60), these values of W_m are all close to the value of 0.11 g of water per g of starch, calculated by assuming that one water molecule sorbs per anhydroglucose unit. Because this calculation assumes that all anhydroglucose units are available for primary binding, and because this is not likely to be precisely the case, it is not surprising that the values measured for W_m are slightly less than 0.11 g/g.

Zografi et al. (61,64) have extended this analysis to the sorption of water by various celluloses. For celluloses, corrections are necessary because only the amorphous regions of cellulose take up water vapor. Table 4 shows the W_m values obtained from isotherm analyses of several cellulosic materials after accounting for the degree of crystallinity. As expected, celluloses with different degrees of crystallinity exhibit different values of W_m

Table 4 W_m Values for various celluloses obtained from BET analysis of moisture uptake isotherms corrected for degree of crystallinity

Cellulose	Crystallinity %	W_m Corr (g/g)	Reference

(From Refs. 61 and 66.)

without correction for crystallinity, and all are considerably less than that for the starches. When corrected, however, for the degree of crystallinity, all of the values are in reasonable agreement with each other and with the W_m values obtained for the starches. Especially interesting are the results in Table 4 for microcrystalline cellulose samples having different degrees of crystallinity due to grinding (66). These results suggest that a similar mechanism of water uptake is occurring in starches and the noncrystalline regions of celluloses.

Similar analyses of moisture uptake data available in the literature for other cellulose and starch derivatives used as pharmaceutical excipients are presented in Table 5. Considering the uncertainties associated with the estimated moisture uptake values from published graphs, the values of W_m are all quite consistent with each other and with a stoichiometry of one water molecule per anhydroglucose unit. It is interesting to note that the two samples derived from cellulose, sodium carboxymethylcellulose and sodium croscarmellose, did not require any correction for degree of crystallinity to conform to close to a 1:1 stoichiometry. It appears quite likely, therefore, that the change in chemical structure and the processing of these materials essentially eliminates the crystallinity of cellulose.

The preceding analysis suggests that water, indeed, penetrates throughout the amorphous regions of these materials and undergoes a specific interaction with available sorption sites, most likely the available hydroxyl groups on the anhydroglucose units. Differential heat of sorption results for various starches (19, 63) and cellulose (10,68) support this model. Data gathered indicates that there is a specific water–solid interaction out to a moisture content of at least the equivalent of 3 times W_m . The water present in this system appears to

exist in a more structured state (i.e., reduced mobility) than bulk water over this range. Interestingly, the heats of sorption exhibit discrete breaks corresponding to stoichiometries of one and two water molecules per anhydroglucose unit. Some differential heat of sorption results are nearly constant over the W_m range, suggesting that binding is homogeneous over this range (10, 19). This is, however, not always the case. This is borne out by heat of vaporization data reported by Etzler and Connors on cellulose samples (70). As measured using simultaneous DSC/TGA, the heat of desorption of water from the matrix continuously increases once the moisture content is less than approximately 0.5 g water/g cellulose (about 3 times W_m). These results suggest that the sorbed water exists in multiple “states” that are energetically distinct.

Other supportive evidence for a specific water–solid interaction is available from thermal studies showing the amount of nonfreezeable water (71–73), nuclear magnetic resonance (39, 74–80), and diffusion studies (81, 82). The evidence is less clear, however, concerning whether there is distinct binding of water to sorption sites with discrete energy levels or whether there is a continuum of states where water interacts to a lesser extent with increasing amount sorbed (61, 83). In any event, it is clear that sorbed water behaves with a considerable degree of mobility, and hence, questions the use of the term “bound water” (61, 84).

Isotherm Analyses as a Function of Temperature

Generally speaking, the absorption of water into amorphous solids as a function of relative humidity decreases as the temperature increases, reflective of an overall exothermic process, normally expected with vapor adsorption processes. Such behavior has been observed with cellulose (85), starch (19), poly(vinylpyrrolidone) (13), and poly(methyl methacrylate) (86). In such cases it is often assumed that the dominant factor is the negative heat of absorption arising from the change in the extent of water binding. The process, however, is made much more complex than this because of the changing morphology of the solid and, hence, an entropy change as well. The complexity of the effects of temperature on water vapor absorption and the possible links to the plasticizing effects of water may be observed in the work of Oksanen and Zografi (13), who have reported that the W_m values for poly(vinylpyrrolidone) over the temperature range of -40 – 60°C decrease by a factor of three, suggesting that W_m does not reflect the absolute number of available binding sites on the polymer for directly “bound” water.

Table 5 W_m Values for various pharmaceutical excipients obtained from BET analysis of moisture uptake isotherms

Excipient	W_m (g/g)	Reference
Starch 1500	0.074	(63)
Sodium starch glycolate (Explotab®)	0.081	(67)
Sodium starch glycolate (Primogel®)	0.092	(67)
Crosslinked dextrose (CLD-2)	0.098	(68)
Croscarmellose, sodium (Ac-Di-Sol®)	0.094	(68)
Sodium carboxymethylcellulose	0.103	(69)

(From Ref. 61.)

Rather, W_m appears to be related to $W(T_g = T)$, the amount of water sorbed that will reduce the glass transition temperature, T_g , to the temperature of the sample, as the ratio of $W(T_g = T)/W_m$ remains nearly constant at 3.0 over the entire temperature range.

In summary, it is clear that water absorbs into amorphous polymers to a significant extent. Interaction of water molecules with "available" sorption sites likely occurs via hydrogen bonding such that the mobility of the sorbed water is reduced and the thermodynamic state of water is significantly altered relative to bulk water. Yet accessibility of the water to all potential sorption sites appears to be dependent on the previous history and physicochemical properties of the solid. In this regard, the water–solid interaction in amorphous polymer systems is a dynamic relationship depending quite strongly on water activity and temperature.

The Meaning of Specific Surface Areas Calculated from Water Absorption Studies

Simply calculating specific surface areas from the W_m values in Tables 3–5 leads to "apparent" specific surface areas of approximately 300–500 m²/g (61, 64). Specific surface areas obtained from similar analyses of nonpolar gas (nitrogen or krypton) adsorption studies, however, are typically in the range of 1 m²/g, independent of sample pretreatment.

Interestingly, the ball milling studies of microcrystalline cellulose by Nakai (Table 4) (66) have shown that the W_m values obtained from water sorption studies increase to a much greater extent than the increase in surface area because of comminution of the sample. In fact, as discussed earlier, moisture sorption was shown to be proportional to the amount of amorphous character, suggesting that water is absorbed throughout the amorphous regions of this substance. In this regard, artifactual specific surface areas are obtained if calculated from water absorption data (64) for these types of substances.

The Role of Water as a Plasticizer

Absorption of significant amounts of water into the internal structure of a solid has been shown to influence the properties of the solid. This is apparent, for example, in the hysteresis observed between the sorption and desorption isotherms in Fig. 4. This phenomenon becomes exaggerated to a greater extent for materials that consist of higher proportions of amorphous material. Levine and Slade

(14, 87) have demonstrated that water, with a very low glass transition temperature, can act as a plasticizer, thereby lowering the glass transition temperature, T_g , of amorphous polymers. Similar behavior is observed in amorphous low molecular weight solids. Recognizing that the viscoelastic properties of the solid are altered significantly above T_g (rubbery state) relative to below T_g (glass or vitreous state), it is likely that the solid will undergo changes of its physical properties at distinct moisture contents and defined temperatures as a result of this phenomenon (13, 14). Oksanen and Zografi (13) have shown with poly(vinylpyrrolidone) that the moisture content at which the moisture sorption isotherm begins to increase significantly correlates very well with the moisture content that will reduce T_g to the temperature of the isotherm. This is illustrated in Fig. 5, which shows water absorption isotherms for poly(vinylpyrrolidone) over the temperature range of -40 to 60°C (13, 88). Clearly, the inflection point at which the isotherm begins

Fig. 5 Water vapor sorption isotherms for poly(vinylpyrrolidone) at 60°C (+); 30°C (x); -20°C (*); -40°C (Δ). Data were taken from Oksanen and Zografi (76, 78). A ◇ represents the calculated water contents necessary to depress T_g to the temperature of the isotherms.

to turn markedly upward shifts to a higher moisture content as the temperature is reduced. To illustrate this, note that the moisture content (0.674 g/g) necessary to reduce T_g to -40°C has not been attained yet in Fig. 5 and the isotherm appears quite linear over the relative humidity range shown. For further clarity, the moisture contents [$W(T_g = T)$] corresponding to T_g at 60, 30, -20°C , and -40°C were shown to be about 0.205, 0.313, 0.553, and 0.674 g/g, respectively. Oksanen and Zografi (13) reported that cellulose and elastin (a protein) exhibit similar relationships, where the glass to rubber transitions correspond to the upward inflections in their respective isotherms.

Subsequent studies by Hancock and Zografi (89) demonstrated that the glass transition temperatures for PVP, hydroxypropyl methylcellulose, and poly(methyl methacrylate) were linearly depressed by the weight fraction of sorbed water, according to the simplified Gordon–Taylor/Kelly–Bueche equation (90):

$$\frac{1}{T_{g(\text{mix})}} = \left(\frac{W_1}{T_{g1}} + \frac{W_2}{T_{g2}} \right) \quad (15)$$

where W_1 and W_2 are the weight fractions of components with T_g values T_{g1} and T_{g2} . The results clearly indicate that the viscoelastic properties of amorphous materials can undergo significant changes as the solid transitions from the glassy to rubbery state. Furthermore, these changes can occur due to elevation of temperature at fixed moisture content or to an increase in moisture content at constant temperature or to a combination of these effects. For dry amorphous substances, molecular mobility of the solid begins to be significantly enhanced relative to the glassy state as low as 50°C below T_g (91). Similar increases in molecular mobility due to the plasticizing effects of absorbed water suggest the need to maintain amorphous systems at least 50°C below the system glass transition temperature to avoid physical, chemical, and/or mechanical property changes over the product shelf life. Some properties that are likely to be affected include tablet compaction (92, 93), gelatin capsule brittleness (14, 94), collapse of lyophilized amorphous powders (88, 95, 96) protein stability (97, 98), and the stability of low molecular weight, moisture sensitive drugs mixed with amorphous polymeric substances (99).

WATER SORPTION BY PHARMACEUTICAL SOLIDS SUBJECTED TO PROCESSING

Understanding the mechanisms of moisture sorption by solids existing in either the crystalline or amorphous

states allows a conceptual estimation of critical points where major changes in physical or chemical properties occur (e.g., RH_0 , a crystal hydration relative humidity, glass transition temperature). Processing (i.e., milling, spray drying, compaction, lyophilization, etc.) of pharmaceutical solids, however, often induces at least partial conversion of most substances to a high energy form (100–107). Such local disorder has been associated with enhanced chemical reactivity (101–108) and increased solubility (15) relative to the thermodynamically favored crystalline state. These regions have been referred to as “hot” spots of the bulk solid and, when present, leave the solid in an “activated state” (15, 100–107, 109, 110–113).

This nonhomogeneity that exists in processed solids complicates the study of moisture sorption phenomena in these materials, as more than one mechanism of uptake must be considered. This is especially difficult, and often frustrating, for cases in which only a small amount of amorphous material is present, as the experimental techniques required to complete these analyses are labor intensive (114, 115). Yet, relatively low percentages of amorphous material can absorb considerable amounts of water into their structure, with these regions undergoing considerable change and a consequent effect on the overall properties of the bulk substance (100). This is especially important for low molecular weight substances that have the ability to readily recrystallize due to their overall greater mobility relative to higher molecular weight polymeric materials. This has been demonstrated for sodium chloride and sodium salicylate ground for 15 min in a mortar and pestle (48). Whereas recrystallized materials exhibited no change in specific surface areas with increasing relative humidities, the ground samples exhibited significant reductions in specific surface areas as relative humidities were increased. Figure 2 illustrates the differing moisture uptake profiles for the recrystallized and ground sodium chloride samples, normalized for specific surface area (48). Whereas the ground material sorbed significantly more water at lower relative humidities than the recrystallized sample, the recrystallized material sorbed greater amounts at higher relative humidities. This relative reduction in sorption capacity of the ground sample is attributed to a reduction in surface area as relative humidity increased, due to the consequent recrystallization of the disordered surface material (48). Fukuoka et al. (116) have demonstrated that a variety of pharmaceutical substances indeed can be made amorphous and, furthermore, exhibit glass transition temperatures over a range from 243 to 354 K. For example, aspirin, progesterone, phenobarbital, and sulfadimethoxine exhibit T_g values of 243, 279, 321, and 339 K, respectively.

Similar to amorphous polymeric systems, low molecular weight amorphous substances also exhibit a reduction in T_g as moisture content increases (117), thereby leading to favorable conditions for recrystallization to occur. Indeed, low molecular weight amorphous solids possess sufficient molecular mobility well below T_g (118). In some systems with multiple solid states possible, the water activity/moisture content can influence the crystallized form of the solid (119). Unfortunately, recrystallization of nonhydrating, low molecular weight amorphous systems can lead to the liberation of significant amounts of water to the headspace (15, 48, 103, 104, 120). Such "moisture dumping" can have additional impact on the physical, chemical, and mechanical properties of the system (17, 48, 100).

To illustrate this more quantitatively, consider the hypothetical sucrose example discussed by Ahlneck and Zografi (100). Assuming that all the sorbed water is taken up by the amorphous portion of material, 0.1% total moisture would correspond to approximately 20%, 10%, 4%, and 2% moisture content in the amorphous material, respectively, for 0.5%, 1%, 2.5%, and 5% of amorphous solid. The glass transition temperatures for the amorphous portions of these systems range from 9 to 49°C, respectively (87,100). Hence, significant changes in the solid state properties are expected at room temperature if relatively small amounts of amorphous material (i.e., < 1%) are initially present. This example illustrates that even for low moisture content materials, significant changes can occur in localized amorphous regions of a solid, which may affect properties of the material influenced by molecular mobility (100).

Inhibition of events resulting from increased molecular mobility due to increased moisture absorption and a subsequent reduction in T_g can be accomplished by formulating such materials with amorphous substances of higher T_g . The net effect is to increase molecular interaction and raise the system T_g to a level where molecular mobility is again sufficiently low (high viscosity) such that the undesired property changes do not occur (107, 121, 122).

The recrystallization of amorphous low molecular weight systems can be convoluted by the impact of structural changes on the material. For example, spray drying α -lactose monohydrate typically produces a material that is completely amorphous as determined by powder X-ray diffraction. However, lactose undergoes anomeric rotation in solution, causing a change in the fundamental structure of the molecule. The impact of this structural change on the uptake and equilibration of water to the amorphous lactose is significant. As expected, an

increase in moisture content will result in the suppression of the glass transition temperature to the point where instantaneous crystallization occurs. However, the material produced is nonuniform as there are two different forms of lactose present, one of which is anhydrous in the crystalline state. Furthermore, at elevated humidity, the crystalline β -anhydrate can undergo structural change in the solid state and produce the α -monohydrate. Evaluation of data gathered needs to be completed in the context of a careful characterization of the possible solid forms (16, 17, 123–125).

TRANSFER OF WATER BETWEEN SOLID COMPONENTS VIA THE HEADSPACE

Combining solids that have previously been equilibrated at different relative humidities results in a system that is thermodynamically unstable because there will be a tendency for moisture to distribute in the system so that a single relative humidity is attained in the headspace. As shown in Fig. 6, moisture will desorb into the headspace from the component initially equilibrated at a higher relative humidity and sorb to the component initially equilibrated at a lower relative humidity. This process will continue until both solids have equilibrated at the final relative humidity. The final relative humidity can be predicted a priori by the sorption–desorption moisture transfer model (SDMT) model (126) if one has moisture uptake isotherms for each of the solid components, their initial moisture contents and dry weights, headspace volume, and temperature. Final moisture contents for each solid can then easily be estimated from the isotherms for the respective solids.

Fig. 6 Schematic representation of moisture transfer between solid components, A and B, respectively. (a) Headspaces isolated from one another; (b) Headspaces allowed to equilibrate. R_A and R_B are initial relative humidities above A and B, respectively; V_A and V_B are headspace volumes above A and B, respectively; R_f and V_T are final relative humidity and headspace volume above A and B, respectively. (From Ref. 126.)

The SDMT model has practical utility in aiding the rational optimization of the initial moisture contents of individual components in a system to attain the final desired relative humidity. Practical applications to date have included adjustment of the initial formulation LODs prior to capsule filling to avoid gelatin capsule brittleness (94, 127), selecting the appropriate formulation moisture content and amount of desiccant to maintain the relative humidity inside a container below a defined value (128), and selection of appropriate dry powder inhaler design and packaging conditions for optimal stability (129).

SUMMARY

Moisture is present in all solid pharmaceutical drugs and dosage forms and in most processing techniques. Understanding where the water resides, its state, and the manner in which it affects the properties of individual materials, their mixtures, and ultimately, final product performance and integrity are essential for the developmental scientist to better understand the role of water in a particular system. Especially important are the kinetics of moisture uptake or loss, "equilibrium" uptake values as a function of relative humidity, whether the water resides externally or is absorbed into the material, its degree of binding with the solid, and the tendency for water to redistribute in a system consisting of more than one solid. Although water-solid interaction(s) can be extremely complex in pharmaceutical systems, application of these fundamental concepts to product development can greatly aid in understanding the role of moisture in affecting the physicochemical properties of solid materials.

ACKNOWLEDGMENTS

The authors thank Professor George Zografi, Dr. Cindy Oksanen, and Dr. Frank Etzler for their technical contributions to this chapter and Ms. Linda Schweikardt for her graphical support.

WAXES

Roland A. Bodmeier

Freie Universität Berlin, Berlin, Germany

INTRODUCTION

The term wax generally refers to a substance that is a plastic solid at room temperature and a liquid of low viscosity above its melting point. Strictly speaking, a wax is chemically defined as an ester of a monohydric long chain fatty alcohol and a long chain fatty acid. However, generally the term wax has been applied to a broad group of chemically heterogeneous materials. Waxes usually contain a wide variety of materials including glycerides, fatty alcohols, fatty acids, and their esters. In the pharmaceutical literature, the terms waxes, fats, or lipids have often been used interchangeably and no consistent terminology has been established. They have in common their lipophilic character and their insolubility in water and solubility in nonpolar solvents. Besides natural materials, many semisynthetic products such as fatty acids or alcohols or surfactants are derived from lipids.

Waxes have been used by the pharmaceutical industry for many years. Their applications in semisolid preparations, including ointments, creams, or lotions, and in suppositories are well known and numerous publications exist on this topic. Because of their lipophilic properties, waxes have been used in sustained-release single or multiple unit solid dosage forms. This article reviews the different uses of waxes as sustained-release carrier or coating materials.

WAXES IN PHARMACEUTICAL DOSAGE FORMS

Waxes are obtained from various sources and are generally classified into animal, insect, vegetable, mineral, and synthetic waxes (1–7).

The most familiar animal wax is probably lanolin, which is obtained from the wool of the sheep. It consists primarily of esters of C_{18} – C_{26} alcohols and fatty acids, sterols (cholesterol), and terpene alcohols. It is frequently used in topical preparations. Until recently, spermaceti was another commonly used animal wax. Spermaceti is obtained through the precipitation of the head oil from the sperm whale on cooling. It consists primarily of cetyl palmitate. Because of public concerns with animal-derived

products, spermaceti has been replaced with other natural or synthetic products.

The most commonly used insect wax is beeswax. It is obtained from the honeycomb of the bee. White and yellow beeswax are GRAS-listed and consist of mixtures of various esters of straight chain monohydric alcohols with even number carbon chains (C_{24} – C_{36}) esterified with straight chain fatty acids. The major ester is myricyl palmitate. Beeswax also contains free acids and carbohydrates. White wax is obtained through bleaching of yellow wax with oxidizing agents or with sunlight. The National Formulary 18 (NF18) (8) specifications list a melting range of 62–65°C, an acid value of 17–24, and an ester value of 72–79. It is practically insoluble in water, sparingly soluble in ethanol, and soluble in chloroform and various oils. Beeswax is used as a stiffening agent in topical preparations, as a stabilizer of w/o-emulsions, and as a polishing agent in sugar coating.

Carnauba wax is plant-derived and is obtained from the carnauba palm tree, indigenous to Brazil. The wax is obtained from the surface of dried leaves. It is widely used in food, cosmetic, and pharmaceutical products. It consists of a complex mixture of high-molecular-weight esters of acids and hydroxyacids. Carnauba wax is very hard and brittle, and has a high melting point. The NF18 specifications list a melting range of 81–86°C, an acid value of 2–7, and a saponification value of 78–95. It is insoluble in water, slightly soluble in boiling ethanol, and soluble in warm chloroform. Besides the sustained-release applications described later, it is used as a polishing agent in sugar coating because of its high gloss, and in topical preparations. Other, less used vegetable-derived waxes include candelilla wax and castor wax.

Hydrogenated vegetable oils are prepared by hydrogenation of refined vegetable oils. Hydrogenated vegetable oil consists of mixtures of triglycerides, with two types being defined in the USP23. Type II includes partially hydrogenated vegetable oils and has a lower melting range and a higher iodine value than Type I. Type I melts in the range of 57–70°C and has iodine value of 0–5, while Type II has a melting range of 20–50°C and an iodine value of 55–80. They are used as lubricants, as sustained-release matrix materials, as viscosity modifiers in semisolid formulations, to enhance

the solidification of suppositories, and to minimize the sedimentation of dispersed drug.

Two commonly used mineral-derived waxes are petroleum wax, which is microcrystalline, and paraffin wax, which is crystalline. They are both obtained from petroleum: the quality and quantity of the wax depends on the source of the crude oil and the refining process. Microcrystalline wax (petroleum ceresin or wax) consists of straight chain and branched saturated alkanes with a chain length range C_{41} – C_{57} . The NF18 specifications list a melting range of 54–102°C; it comes in plastic and hard grades. It is insoluble in water, slightly soluble in ethanol, and soluble in chloroform. Besides its use as a sustained-release carrier, it is used as a stiffening agent in topical preparations. Because of its high viscosity and melting point, it increases the consistency of creams and ointments. Paraffin wax (hard paraffin) is a mixture of solid straight chain alkanes. It is used in ointments or creams as a base or stiffening agent. It congeals between 47 and 65°C. Various grades with different melting ranges are available. It is insoluble in acetone, ethanol, and water and soluble in chloroform and most warmed fixed oils. Low-molecular-weight polyethylenes ($MW < 10,000$) have wax-like properties and are used in topical preparations, for example, as gelling agents in Plastibase.

CHARACTERIZATION

Because the harvesting of vegetable or insect waxes is often from wild, noncultivated sources and because of their complex composition, it is important to characterize the chemical and physical properties of the waxes (1–6). The composition of natural materials often varies with location, weather, season of harvesting, and age. A good quality control of the raw materials is of utmost importance in order to obtain pharmaceutical products of high quality.

The chemical methods to characterize waxes include the determination of the acid, saponification, iodine, hydroxyl, and peroxide values. Various tests, often yielding different values, are available to measure the melting point of waxes. Since waxes are nonhomogeneous in chemical composition, a melting range rather than a clear melting point is most observed. The melting point of glycerides generally increases with increasing hydroxyl number, decreasing degree of unsaturation, and increasing molecular weight of the fatty acid. The melting point of many waxes can be determined with capillary tubes. The slip point is defined as the temperature at which a column of the testing material starts raising in an open-ended capillary tube, which is dipped in water filled in a beaker

and heated under specific conditions. The drop-point test can be used; however, it is not reliable for more viscous waxes. The congealing point of a wax is the temperature at which the molten wax stops to flow upon cooling. Thermal methods such as differential scanning calorimetry (DSC) are widely used to characterize the heating and cooling profiles of waxes in a qualitative and quantitative manner. Potential polymorphic transitions and recrystallization during processing can be simulated by running different temperature profiles.

The contraction of suppository bases during cooling within the mold is a well-described phenomenon. The expansion or contraction of waxes is also important during the processing of wax melts, for example, during the preparation of microparticles by spray congealing, hot-melt coating, or hot-melt filling of hard gelatin capsules. The dilatation of waxes or thermal expansion during the transition from the solid to the liquid state can be measured with a dilatometer. The hardness of a wax is measured with a penetration test, whereby the depth of penetration of a needle under a given weight is measured, preferably at different temperatures. The viscosity of the molten wax is an important parameter, especially for processes such as hot-melt coating or spray congealing, where wax melts are processed. In an ASTM monograph (D 88), the time that a certain quantity of molten wax requires to flow through an orifice of specified dimensions is measured.

The color of the wax will affect the color of the finished product. A Lovibond Tintometer is often used for color measurements, whereby the color of the raw material is compared against a series of colored standard glasses, under a standard light source. The color of the solidified wax of the same sample may be different depending on the amount of occluded air, the rate of cooling, or surface finish. Therefore, the color of many waxes is best measured in the molten state. Two ASTM color standards are used to measure dark-brown to off-white color and off-white to pure white. The refractive index and the specific gravity are other parameters often determined.

The structural and physical properties, in particular, the solid and liquid state behavior of lipids, and the optical and spectral characteristics of waxes have been described in detail (4).

PHARMACEUTICAL APPLICATIONS

Waxes in Matrix-Type Drug Delivery Systems

The incorporation of drugs into inert matrices is a popular approach to prolong the drug release. Sustained-release wax matrix drug delivery systems include wax granules or

beads prepared by granulation or extrusion/spheronization, tablets, and wax-filled hard gelatin capsules.

Wax Granules and Beads

Drug-containing wax granules were prepared by melt congealing, by congealing in chloroform, by granulation, and by aqueous dispersion (9–11). In the congealing method, the drug was suspended in the molten wax. This suspension was cooled gradually while stirring until a solid mass formed, which was then comminuted into granules. Granules made by congealing in chloroform were prepared similarly, the drug being suspended in a chloroformic solution of the wax. This mixture was agitated until the solvent evaporated, and was then comminuted into granules. In the granulation method, the powdered wax and drug were granulated with chloroform. In the last method, heated water was given to the molten drug–wax mixture until phase inversion occurred. The emulsion was cooled and the particles were separated from the aqueous phase by filtration. The melt-congealing method gave the largest retardation in drug release, probably because of the denser structure of the granules when compared to granules prepared by the other methods.

Sustained-release nitrofurantoin granules containing stearic acid and glycerol monostearate as matrix materials were prepared by either a fusion, solvent evaporation, or melt granulation technique (12). Various channelling agents including Aerosil, Avicel, dibasic calcium phosphate dihydrate (Emcompress), and sodium chloride were investigated in order to increase the drug release. In the fusion method, the lipid was melted and the drug was added to the melt. After cooling, the congealed mass was granulated through standard sieves. In the solvent evaporation method, the drug and the wax carriers were dissolved in dimethyl formamide. The solution was cast and the solvent was evaporated at 70°C. The resulting mass was granulated as described previously. In the melt granulation method, the drug and carriers were mixed at high speeds; the temperature increased by friction and granulation occurred by sintering of the fatty materials near their melting point. The cooled granules were crushed and sieved. Sustained release could only be obtained with granules prepared by the fusion method. The solvent evaporation method and, surprisingly, melt granulation resulted in granules with a fast drug release.

Drug-containing beads were prepared by extrusion/spheronization of powder blends of 10% drug (chlorpheniramine maleate or acetaminophen), 60% Avicel PH-101, and 30% wax (13). Thermally treating the beads at 80°C for 30 min resulted in the melting and recongealing of the

wax within the beads and in a decrease in the drug release, probably because of a densification and redistribution of the wax within the beads. The drug release was dependent on the treatment temperature and the level of the wax, with an increase in both resulting in a decrease in drug release. The beads were subsequently compressed into tablets, which had slower release rates when compared to the release from the corresponding beads. While nontreated compacts mainly disintegrated into the beads, thermal treatment of the compacts resulted in nondisintegrating matrices.

Diclofenac sodium–carnauba wax matrix granules containing various release-controlling agents such as hydroxypropylcellulose, Eudragit L-100, or NaCl were prepared with a twin-screw extruder and evaluated in vitro and in vivo (14, 15). The drug release depended strongly on the composition of the granules: the mechanical strengths of the wetted granules was high, and a good correlation was obtained between in vitro dissolution parameter and in vivo parameters.

Wax Matrix Tablets

Wax matrix tablets are prepared either by compression of the wax granules or beads described in the previous section, or, with the higher melting waxes available in powder form, by direct compression of powder blends. When compared with polymeric matrix materials, the amount of waxes within the tablet is limited because of fusion and sticking to the punches at higher wax concentrations. This problem could possibly be overcome by compression at lower temperatures.

Matrix tablets containing ephedrine hydrochloride and hydrogenated castor oil were prepared either by compression of a physical mixture or by compression of a congealed melt (16–18). In the second method, the drug was added to the molten hydrogenated castor oil at 100°C, this molten mass was poured onto a glass plate and congealed, comminuted and then compressed into a matrix. A surfactant, 0.1% alkyltrimethylammonium bromide, was added to the dissolution medium to enhance the wetting of the wax matrix. The drug release increased with increasing amounts of drug in the matrix because of an increased porosity, and followed the square root of time relationship (Fig. 1). The release was slower from the matrix prepared by the melt method. This was attributed to a higher tortuosity and lower porosity of the melt matrix when compared to the matrix prepared from the physical mixture. Increasing the pressure decreased the release rate with both preparation processes; however, the effect was much more pronounced for the matrix prepared from

Fig. 1 Effect of concentration of ephedrine hydrochloride on release from matrixes compressed at 7 MPa (48,265 psi). (○) 5%; (●) 10%; (△) 20%; (▲) 30%; (□) 40%; (■) 50%. (From Ref. 17.)

the physical mixture. The processing method also altered the mechanism and rate of release; a matrix diffusion mechanism was dominant with the melt process while a boundary layer diffusion was effective with matrixes prepared by the compression of physical mixtures. In the first case, the drug release was independent of stirring speed, while it was dependent in the second case.

Sustained-release nifedipine tablets based on Gelucires were developed (19). A drug-PVP coprecipitate was either added to a solution of Gelucire in chloroform with the subsequent removal of the solvent or it was added to the molten Gelucire with subsequent cooling of the paste. The mixtures were then granulated through a 0.5-mm sieve and tableted. No difference in the release profiles from the two granulates were observed; however, the melting method was preferred because of the absence of organic solvents. Accelerated stability studies on the tablets as a function of temperature and relative humidity revealed no changes in chemical stability; however, the dissolution profiles changed. The changes occurring after storage at high humidities and temperatures were attributed to the formation of nifedipine microcrystals and to structural changes in the wax vehicle.

A combination of ethylcellulose and paraffin wax or hydrogenated castor oil was used as carrier material in sustained-release aminophylline tablets (20). The tablet granulation was prepared by a wet granulation procedure with hot ethanol. The tablets were further coated with Eudragit RL/RS or HPMC/ethyl cellulose. An annealing step at 70°C significantly decreased the drug release due to fusion within the tablet core. Hydrogenated castor oil was superior to paraffin wax. Increasing the wax content and

decreasing the amount of ethyl cellulose or increasing the drug content resulted in faster drug release.

In order to overcome the disadvantage of hydrophilic matrixes of uncontrollable erosion of the hydrated polymer gel on the tablet surface, a combined polymer-wax carrier material was evaluated by Huang et al. (21). Carnauba wax was combined with the enteric acrylic polymer, Eudragit L 100, and investigated as a carrier material for diphenhydramine HCl. The drug and Eudragit L100 were mixed, added to the molten wax, followed by compression of the congealed granules. The polymer provided an insoluble structure for the wax. The drug release was significantly retarded with increasing amounts of the anionic polymer. The cationic drug, diphenhydramine HCl, interacted with the anionic Eudragit L within the wax matrix and formed a complex after water penetration. While the drug release from tablets prepared from only the drug and the enteric polymer was highly dependent on the pH of the dissolution media, the drug release was almost independent of pH after the inclusion of carnauba wax in the matrix. Besides the retarding effect of the wax, at low pH, the release was retarded through the enteric polymer and at high pH, the drug formed a less soluble complex with the enteric polymer, thus negating the effect of pH on the drug release.

Matrix minitabets based on starch/microcrystalline wax mixtures were prepared by melt granulation in a hot-stage screw extruder, followed by milling and compression (22). This technique was preferred over the production of pellets.

Surfactants were incorporated into wax matrixes in order to increase drug release (23). The drug and surfactant were added to a molten mixture of carnauba wax and stearyl alcohol. Water-insoluble surfactants such as glycerol monostearate had no effect on the dissolution rate, slightly soluble surfactants such as sodium stearate or dioctyl sodium sulfosuccinate moderately increased the drug release, while polyoxyethylene 23 lauryl ether significantly increased the drug release. The drug release occurred via a leaching mechanism; drug diffusion through the matrix did not occur. It was speculated that the surfactant created more channels for the drug to leach into the dissolution medium by increasing the porosity of the matrix.

While the drug release from wax matrix tablets followed the square root of time relationship, approximately zero-order release of ephedrine hydrochloride and procaine hydrochloride could be obtained with multi-layered matrixes of hydrogenated castor oil containing different concentrations of the active compound in each layer (24).

A bioadhesive lozenge containing cetylpyridinium chloride was developed based on a multilayered tablet (25). One layer contained the bioadhesive polymer, carbopol, and the other layer contained the drug and a wax (spermaceti or Precirol ATO-5).

Wax Implants

Besides polymers such as polylactides, waxes have the potential as biocompatible/biodegradable carriers in implants. Standard tableting equipment can be used to prepare wax compacts.

Various lipids including triglycerides (e.g., trilaurin, trimyristin, tripalmitin and tristearin) and fatty acids were evaluated as carrier materials in sustained-release insulin implants (26). The drug/wax powder blend was compressed into a disc and implanted subcutaneously into Wistar rats. Monoglycerides tested eroded too fast and were not suitable. The triglycerides only sustained the insulin release briefly. The best sustained-release properties were obtained with palmitic and stearic acids as the carrier materials.

The drug release of the model protein, bovine serum albumin (BSA), from compressed stearic acid pellets was investigated as function of drug loading, drug and carrier particle size, and compression force (27). At low loadings (5%), the drug release increased with increasing BSA particle size irrespective of the particle size of stearic acid. At high loading (20%), the drug release was higher with larger stearic acid particles. More BSA was released with increasing BSA particle size only when the stearic acid particle size was small. The compression force did not show any effect in the range investigated. In a series of articles, the same research group investigated cholesterol–lecithin implants as a delivery system for antigens (28–31).

Labrafil 1944 CS (derivatized vegetable oil)–Precirol ATO 5 (glyceryl ester of fatty acids) gels were shown to be biocompatible and biodegradable and resulted in controlled release of steroids for prolonged periods of time in vivo (32).

Hard Gelatin Capsules Filled with Waxes

Waxes are difficult to compress at higher levels. The energy imparted during compaction causes melting of the waxes, resulting in sticking and picking of the formulation. This necessitates dilution of the drug-wax granules with inert fillers; high-dose drugs requiring high amounts of wax in order to obtain sustained-release properties are therefore difficult to formulate into tablets. As an alternative to

compressed tablets, hard gelatin capsules have been liquid-filled with solutions or dispersions of drugs in molten waxes. On cooling, drug–wax plugs are obtained. Some of the advantages of liquid filling of hard gelatin capsules, when compared to solid-filled capsules, include a better weight uniformity, and the elimination of dust hazards and cross-contamination via airborne particles. The drug–carrier system should not interact with the gelatin shell in the molten as well as in the congealed state, and the physical state of the drug and wax should not change during storage. The melting point of the wax has to be low enough to avoid degradation of the drug and damage to the capsule shell.

A Zanasi hard gelatin powder filling capsule machine (model LZ64) was modified in order to allow the filling of molten or thixotropic formulations into hard gelatin capsules (33, 34). This technique resulted in excellent fill weight uniformity and overcame many of the problems frequently associated with the filling of conventional capsules.

The release of liquid or deliquescent drugs (benzonatate, nicotinic acid, chloral hydrate, and paramethadione) incorporated into Gelucire bases within hard gelatin capsules was related to the behavior of the carriers in simulated gastric fluid (35). Gelucires are semisynthetic glycerides with varying amphiphilic properties and are derived from natural hydrogenated food grade fats and oils. They are characterized by their melting point (range: 33–64°C) and HLB value (range: 1–13). The drugs were released faster from the Gelucires with the higher HLB value and with lower melting points. The Gelucires either dissolved completely or remained intact but softened.

It is well known that wax-based dosage forms can experience physical instabilities. Suppository bases often show an increase in melting point, accompanied by a hardening process. This hardening can result in a reduced release rate, which could also affect the in vivo performance. Melt-filled hard gelatin capsules were evaluated by DSC, dissolution, and hardness properties as expressed by a relative penetration (36). Ketoprofen dissolved in the wax, Gelucire 50/13, and apparently formed a solid solution at room temperature as indicated by the absence of crystalline drug by DSC and microscopy. The melting point of the wax increased during storage and was accompanied by a hardening process. However, the release rate increased, which was attributed to an increased rate of matrix erosion. The observed in vitro changes did not affect the in vivo performance of the wax matrix.

As an alternative to hot-melt filling of capsules, sustained-release wax matrices were formed in a novel way within hard gelatin capsules through fluidization in a heated air stream within a fluidized bed (37). A drug–wax

powder blend was filled into hard gelatin capsules, which were then suspended in an upward-moving, heated airstream and circulated within the chamber of a fluidized bed unit. The capsules rotated during fluidization at temperatures above the melting point of the wax and centrifugal forces caused the drug-wax melt to flow into the ends of the capsules. The molten mixture then solidified after ending the heating and two solid wax matrices with dissolved/dispersed drug were obtained in the ends of the capsules. Good control over the drug release was obtained by using blends of waxes with different amphiphilic properties (HLB-values). Gelucire 50/13 (m.p. = 50°C, HLB = 13) and Precirol ATO-5 (m.p. = 53°C, HLB = 2) were selected as the drug carriers. The drug release increased with increasing proportion of the more hydrophilic wax. After cooling of the drug-containing wax melt, the drug could be dispersed, dispersed/dissolved, or dissolved in the wax matrix. DSC studies were used to characterize the physical state of the drugs after formation of the wax matrix. A linear relationship existed between the heat of fusion and the amount of drug in the wax matrix (Fig. 2). The solubility of the drug in the matrix at its melting point corresponds to the intercept of the line. Propranolol HCl was insoluble and dispersed in the Precirol ATO-5 matrix while theophylline was partially dissolved in the wax.

Coating with Waxes

Besides their predominant use in matrix preparations, waxes have also been used as coatings for granules and pellets. Solid dosage forms are often coated to sustain the

Fig. 2 Relationship of propranolol HCl and theophylline loading and the heat of fusion. (From Ref. 37.)

drug release, to improve the stability, or to mask the taste of poorly tasting drugs. The coating with waxes has various advantages when compared to the coating with polymer solutions or dispersions. The waxes can be applied without organic solvents, and, in the case of hot melts, with a high application rate and therefore shorter processing time. Many food grade natural or semisynthetic waxy materials are available.

Waxes can be applied onto solid dosage forms in the form of hot melts, hot emulsions, aqueous suspensions (colloidal wax particles), or organic solutions. Coating processes include dip coating, pan coating, or fluidized-bed coating. The coating of drug particles by spray congealing is discussed in the section on microencapsulation with waxes.

Coating with Hot Melts

With regard to coating processes, various fluidized-bed techniques and their modifications were evaluated for hot-melt coating (38–40). The fluidized-bed techniques include the top, bottom, and the tangential spray or rotary fluidized-bed modes. The particles to be coated are suspended in a heated high-velocity air stream, and the molten wax is applied in the form of atomized liquid droplets.

The top spray mode, in which the wax melt is sprayed downward on upward moving particles, is the system of choice for hot-melt coating (Fig. 3). The product temperature can be kept closest to the congealing temperature of the wax when compared to the other two spray modes. The wax has to be kept in a molten state in

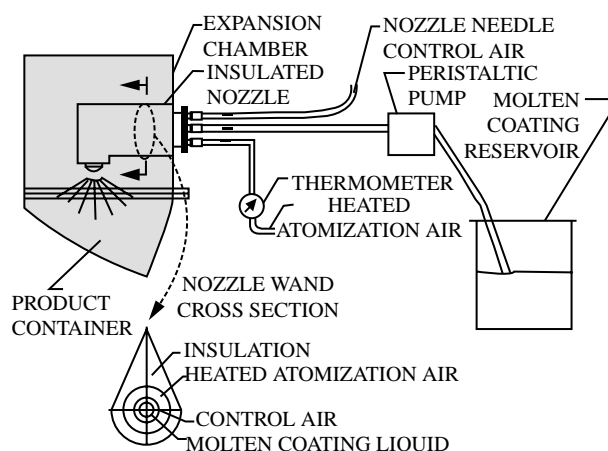

Fig. 3 Insulated nozzle and wand for top-spray hot-melt coating. (From Ref. 38.)

order to be atomized into the fluidized bed. A special nozzle had to be developed. The nozzle wand had a triaxial structure with a center tube for the molten liquid, which is surrounded by a small air space for the delivery of high-pressure, low-volume air to control the valve in the nozzle, which opens when the pump was running. Both of these tubes were surrounded by a larger air space through which the heated atomization air was supplied. The nozzle should be placed as closely as possible to the substrate bed in order to minimize the distance that the molten droplets had to travel prior to contacting the substrate surface.

Substrates with poor fluidization characteristics such as larger particles and/or particles of higher density are difficult to coat with the top spray mode, and the bottom spray mode should be preferred. With the tangential spray process, the product temperatures have to be maintained lower than with the top spray technique in order to avoid adherence of the coated particles to the product container. The tangential spray method is more stressful on the substrates than the other two techniques.

Important process and formulation variables include the product bed temperature, the atomization conditions, the type of substrate, the properties of the coating materials, and the desired release rates (immediate or sustained release). In order to obtain good coatings, the atomization air has to be heated to the same temperature as the molten wax in order to avoid premature congealing. The droplets must remain in a liquid state until they hit the substrate surface. The product bed temperature is very critical to the successful coating of solid dosage forms with molten materials. At low product temperatures, premature congealing of the molten droplets results in poor spreading of the coating on the substrate surface and, in the extreme case, in the failure of the adherence of the coating to the surface. Rough and porous surface structures are obtained, resulting in faster drug release when compared to substrates with smooth coatings. At too high product temperatures, excessive particle agglomeration or clogging of the outlet filter bags is a result of inadequate congealing and hardening of the coating. The product bed temperature can be regulated through the fluidization air temperature. It is recommended to use inlet air temperatures 10–15°C below the melting point of the coating and temperatures for the atomization air and the molten wax of 40–60°C above the melting point.

Droplet size and uniformity are also critical for a successful coating process. The size of the molten droplet is dependent on the viscosity of the melt and the atomization air pressure. Smaller particles require smaller droplet sizes and therefore higher atomization air pressures in order to minimize agglomeration or granulation. In order to obtain small droplets, the viscosity of

the molten material can be decreased by increasing the temperature of the melt. At the same atomization conditions, low feed rates also result in smaller droplets. The spray rate of melts is generally much lower when compared to coating solutions or dispersions. The lower spray rate, however, is offset by the application of pure coating material. The application rate therefore is still higher when compared to polymer solutions or dispersions, with which solvents have to be evaporated.

After the application of the melt, the fluidization is reduced and the product bed is cooled. The cooling circle should be short in order to avoid attrition of the coated product. Rapid cooling, however, may result in cracks in the coating because of contraction of the coating material, and it may also result in unstable polymorphic forms of the wax.

The important variables for the selection of the waxes include the melting point, the melting range, and the viscosity of the melt. The wax should have a melting point of less than 85°C because the melt is usually kept at temperatures of 40–60°C above its melting point. Materials with a broad melting point range can become tacky during spraying because of the broad range of product temperatures and the presence of low melting point fractions. The coating materials include various hydrogenated vegetable oils, beeswax, paraffin wax, carnauba wax, and polyethylene glycol.

Coating with hot emulsions, aqueous suspensions, or organic wax solutions

The coating with hot emulsions has various advantages when compared to the hot-melt process (41, 42). The wax remains in the molten state and premature congealing of the wax could be eliminated because of the presence of hot water. This facilitated the transport of the wax to the spray nozzle and therefore the experimental setup. In addition, the temperatures of the wax emulsion are lower than the comparable wax melts. o/w-Emulsions of various waxes (e.g., glyceryl behenate-Compritol-888 and glyceryl palmitostearate-Precirol-ATO 5) with a solids content of up to 50% were prepared. The emulsions were passed through a microfluidizer to further reduce the particle size of the oil phase. The hot emulsion was then either sprayed directly on the beads or cooled to form a “wax pseudolatex” prior to the coating process. The disadvantages, when compared to hot-melt coating, include the amount of water to be evaporated and therefore longer processing times, and the presence of surfactants in the wax coating. The surfactants, which were needed to stabilize the emulsions, could affect the drug release. The use of liquid surfactants such as various Tween/Span combinations resulted in sticky beads. Solid surfactants such as sodium lauryl sulfate were more suitable. The guaifenesin release from coated

pellets decreased with increasing hydrophobicity of the wax and increasing coating level. The coating conditions (e.g., temperature, spray rate, curing) and the particle size of the emulsion/suspension primarily influenced the microstructure of the wax coatings and hence the drug release. When compared to polymer coatings, thicker coatings have to be applied with waxes to obtain the same sustained release profiles.

Bagaria prepared emulsions with waxes including carnauba, paraffin, ceresin, beeswax, and hydrogenated castor, soybean, or cottonseed oil, which were then coated onto drug-containing nonpareil beads (43). The term emulsions was actually misleading because the final products were aqueous suspensions of the waxes with partially submicron particle size (wax pseudolatex). Similar to aqueous polymer dispersions, the wax dispersions were converted into powders by spray drying. The release from beads coated with the redispersed spray dried powder was then compared to beads coated with the original dispersion. With almost all preparations, 100% drug was released within 2–4 h.

Like with organic polymer solutions, the wax can be dissolved in an organic solvent and then be sprayed onto the solid dosage form. In most studies, waxes such as beeswax, hydrogenated castor oil, microcrystalline wax, or glyceryl mono- and distearate were dissolved in chlorinated organic solvents such as chloroform, carbon tetrachloride, or trichlorethane and applied in coating pans at elevated temperatures (44–46). Mixtures of ethyl cellulose with different waxes such as castor, carnauba, or paraffin wax in chloroform were evaluated as sustained-release coatings (47). A lower ratio of ethyl cellulose to wax was used with drugs of high-molecular weight and/or low solubility and a higher ratio for drugs of low-molecular weight and/or high solubility to achieve the desired release properties at a 10% coating level. As the data of the references shows, the coating with organic solutions is obsolete because of the undesirable use of organic solvents.

Microencapsulation with Waxes

Wax microparticles have been prepared primarily by aqueous and nonaqueous melt dispersion techniques or spray congealing/spray drying. These techniques are briefly reviewed below.

Microparticles prepared by melt-dispersion techniques

In the melt dispersion technique, the drug-containing molten wax phase is emulsified into a heated, emulsifier-containing external phase. Depending on the solubility of the drug, the external phase can be either aqueous (for

water-insoluble drugs) or nonaqueous (for water-soluble drugs). On cooling the emulsion, the liquid droplets congeal and a suspension of the wax microparticles is formed. The microparticles are then separated, mostly by filtration or centrifugation, sometimes washed to remove free drug crystals and surfactants, dried and sized.

Ibuprofen-wax (carnauba wax, paraffin wax, beeswax, Gelucire 64/02, or Precirol ATO5) microparticles were characterized with respect to drug loading and morphological and release properties (48). Microparticles of the more hydrophilic waxes, Gelucire 64/02 and Precirol ATO5, could be prepared without surfactants, while the other waxes rapidly coalesced and formed big lumps on cooling. With the other waxes, increasing the amount of sodium lauryl sulfate in the external aqueous phase decreased the drug loading because of drug solubilization. This was not the case when poly(vinyl alcohol) was used as stabilizer. During emulsification, the drug will partition into the external aqueous phase until its solubility at the emulsification temperature is reached. During cooling of the emulsion, the drug could precipitate in the aqueous phase because of a decreased drug solubility. The type of wax, the rate of cooling, the stirring time, and the temperature of the aqueous phase had no significant effect on the drug loading because of the low solubility of ibuprofen in the external aqueous phase. Actual drug loadings close to 60% could be achieved. The drug release was controlled by the hydrophobicity of the wax (Gelucire 64/02 > Precirol ATO5 > beeswax > carnauba wax > paraffin wax) (Fig. 4). These wax microparticles could be

Fig. 4 Ibuprofen release from different wax microparticles (actual drug loading): (■) Precirol ATO5 (35.3%), (□) Gelucire 64/02 (35.4%), (▲) beeswax (37.7%), (△) carnauba wax (37.3%), (◆) paraffin wax (35.0%). (From Ref. 48.)

formulated into aqueous sustained-release oral suspension dosage forms because of the low solubility of the drug.

A modified USP method using mini baskets was used to study the effect of formulation variables, such as type of wax, type of modifier, drug loading, size, on the ibuprofen release from wax microspheres (49). The drug release was in the order of beeswax > ceresine wax > refined paraffin wax > microcrystalline wax. After an initial burst release, the drug release was slow from microparticles prepared with the last two waxes. The dissolution studies were performed in simulated intestinal fluids, because sink conditions could not be maintained in simulated gastric fluids because of the drug solubility. To increase the drug release from the wax microspheres, glycerol monostearate or stearyl alcohol were added prior to the preparation of the microparticles. The addition of these release modifiers also reduced the tendency of the waxes to agglomerate (50). Ibuprofen dissolved in the molten wax and did not crystallize during congealing and microsphere formation, as indicated by DSC studies.

In a modified melt-dispersion method, sulfamethoxazole particles were dispersed in heated water, and powdered beeswax was added. The molten wax droplets collected the drug particles, and spherical agglomerates with sustained-release properties were obtained after cooling. Alternatively, the agglomerates could also be formed at room temperature by using solutions of the wax in a water-immiscible solvent (51).

Water-soluble drugs cannot be encapsulated with the O/W-emulsion technique because the drug would be lost to the external aqueous phase. Two methods have been described for the encapsulation of hydrophilic drugs; one is based on using an external oil phase and the other one on the formation of the microparticles by a w/o/w-melt dispersion technique.

Carnauba-wax microspheres containing 5-fluorouracil for chemoembolization were prepared by a melt dispersion process with an external silicone oil phase (52). The drug was dispersed in the molten carnauba wax and emulsified into silicone oil at temperatures above the melting point of carnauba wax (85°C). The resulting emulsion was cooled through the addition of cold silicone oil and immersion of the beaker in an ice-water bath. After solidification, the microspheres were separated from the oil phase by centrifugation and washed with cyclohexane to remove the silicone oil. 5-Fluorouracil is a hydrophilic drug; an external aqueous phase would have resulted in drug partitioning and therefore low encapsulation efficiencies. However, even with silicone oil, an external phase in which the drug was insoluble, only up to 5% drug could be encapsulated within the carnauba-wax microspheres. This was attributed to the poor wetting of the drug crystals by

the molten wax and therefore the loss of drug crystals to the external silicon oil phase. Various surfactants were added to the wax phase in order to improve the wettability of the drug by the molten wax.

A technique based on the formation of a multiple emulsion with an external aqueous phase was developed for the encapsulation of water-soluble drugs in order to replace the external oil phase (53). Possible unwanted interactions between the oil and the emulsified wax such as swelling or dissolution of the wax, clean-up requirements of the final product, and recovery of the oil phase could be eliminated. In analogy to the encapsulation of water-soluble drugs within polymeric microparticles by a w/o/w-solvent evaporation method, a molten wax phase was used instead of an organic polymer solution. A heated aqueous solution of pseudoephedrine HCl was emulsified into the molten carnauba wax, followed by the emulsification of this w/o-emulsion into a heated external aqueous phase. The temperature of the internal and external aqueous phases had to be kept above the melting temperature of the wax in order to avoid premature congealing and to assure the formation of an emulsion. The microparticles formed after congealing of the wax. A key for high encapsulation efficiencies was the formation of ultrafine internal aqueous phase droplets by sonication. The wax acted as a diffusion barrier between the internal and the external aqueous phases and therefore minimized drug partitioning into the external aqueous phase. Because of the high solubility of the drug in the external aqueous phase, the contact time of the droplets/microparticles with the continuous aqueous phase had to be minimized in order to avoid the drug loss; the microparticles were separated from the aqueous phase within minutes after their formation.

Generally, the wax phase is emulsified into a heated external phase to avoid premature congealing. However, sulfamethazine-japanese synthetic wax particles were prepared by dispersing the drug in the molten wax, followed by slowly pouring the wax phase into a precooled external aqueous phase (54). The microparticles were then separated by filtration after 3 min. Beeswax microparticles were prepared by a phase inversion technique, whereby an aqueous solution of sorbitan monooleate and polysorbate 80 was added to the drug-containing molten wax phase to first form a w/o-emulsion prior to phase inversion. Smaller microparticles were obtained at higher temperatures, with increased amounts of continuous phase, with slower rates of cooling, and with higher speeds of mixing (55).

Suspensions of lipid nanoparticles can be prepared by reducing the size of the molten or dissolved drug containing lipid phase into the colloidal size range by high-pressure homogenization (56, 57). After cooling or solvent evaporation, the nanoparticles are obtained.

The suspensions of the nanoparticles can be converted into powders through freeze or spray drying. The nanoparticles can act as carriers for poorly water-soluble drugs and apparently could result in controlled release over longer periods of time. However, because of the small size and therefore high surface area of the particles, an increase in dissolution rate would be expected unless very low loadings are used.

Microparticles prepared by spray drying and spray congealing

Similar to organic polymer solutions, drug-containing organic wax solutions were spray dried to give sustained-release microparticles (58). The drug could be either dissolved or dispersed in the organic wax solutions. Spray drying is a single step, rapid drying process, which can be scaled up and be used for heat-sensitive drugs. The use of organic solvents, however, is undesirable because of solvent hazards, solvent residuals, and cost. Because of the low melt viscosity, wax microparticles can also be prepared without organic solvents by spray-congealing drug-containing wax melts.

Sulfaethylthiadiazole-hydrogenated castor oil particles were prepared by spray congealing, using a centrifugal wheel atomizer (59). The wax powder was then suspended into water to give an oral sustained-release suspension. In a subsequent article, the effect of various process and formulation variables on the particle size was investigated using a centrifugal wheel atomizer (60). The particle size was directly proportional to the feed rate and inversely proportional to the feed viscosity and the wheel velocity.

In a series of publications, sulfaethylthiadiazole-wax microparticles prepared by spray-congealing were evaluated. The most important factor affecting the drug release was the type of wax used (61). The effect of surfactant on the drug release from spray congealed wax microparticles was investigated by John and Becker (62). White wax-USP, a synthetic wax-like ester, and 1:1 combinations of these two waxes were used as sustained-release matrices. The particle size of the microparticles could be controlled through the nozzle size, with the larger nozzles resulting in larger particles with slower rates of dissolution. Up to 4% sorbitan monooleate apparently softened the particles and promoted wetting, thus resulting in an increase in drug release. However, at a surfactant level of 10%, the slowest release rate was observed. This was partly attributed to the tackiness of the particles, which resulted in agglomeration and a reduction in total surface area available for drug release. The addition of the surfactant allowed the compression of the microparticles into tablets, which was difficult with the surfactant-free microparticles (63). The surfactant-free microparticles adhered or stuck to

the punch surface, and resulted in a high friability of the finished tablets. No additives were incorporated into the tablets; nondisintegrating wax matrix tablets were obtained.

A palatable suspension of the bitter-tasting drug, remoxipride, was developed based on microparticles prepared by spray congealing (64). Because of the high water solubility of the drug, the microparticles were formulated into an external oil phase. Unfortunately, neither the nature of the wax nor of the oily vehicle was revealed.

With lipid drug delivery systems, polymorphic transformations may occur during the preparation of the dosage form and during subsequent storage. The polymorphic behavior of lipid micropellets prepared from glycerides and phospholipids by spray drying or spray congealing and their surface structure were evaluated by DSC and scanning electron microscopy (65–67). The rapid solvent evaporation during spray drying can influence the crystallization of the lipid carrier and different polymorphic structures could be obtained. Similarly, during spray congealing and solidification of the melt, the lipid can crystallize in different polymorphic forms, depending on the composition of the lipid and the cooling rate. The major polymorphic forms of the glycerides are the α -, β -, and β' -forms. Rapid cooling rates generally result in the unstable α -form. The transition of the melt first to the α - and β' -forms and then to the β -form represents the transformation of triglycerides into the most stable form.

The spraying process, especially the spray congealing was simulated by cooling the molten samples rapidly at 320°C/min. A DSC thermogram of pure tristearin heated at 10°C/min revealed a single endothermic peak representing the β -form. After rapid cooling of the melt and reheating, an endothermic peak for the α -form and an exothermic peak indicating the recrystallization of the α -form into the β -form, followed by the endothermic peak for the β -form, were detectable. The DSC thermogram of spray-dried tristearin micropellets was similar to the one of the melt-quenched sample. A crystalline modification therefore took place during spray drying because of the rapid solvent removal. The micropellets were then stored at different temperatures to investigate the effect of storage temperature on the polymorphic transitions. Increasing the storage temperature to 37°C resulted in a complete transformation of the unstable polymorphic form into the stable polymorphic form. The melting endotherm of the α -form disappeared. The effect of various emulsifiers such as lecithin or monoglycerides was investigated in order to prevent or delay the transformation of the unstable form into the stable

β -form. Adding lecithin to the formulation resulted in a delay of the transformation. The type of glyceride (composition and chain length), solvent, and drugs encapsulated affected the polymorphic transformation, its rate of transformation, and also the surface structure of the microparticles. Spray-congealed lipid micropellets showed a similar thermal behavior as the spray-dried pellets. The smooth surface of the sprayed lipid micropellets was attributed to the unstable polymorphic form. The unstable α -form has various thin and small crystals, resulting in a smooth surface of the crystallized sample. The β - and β' -forms have larger crystals, therefore causing irregular structures of the micropellets. During ageing at elevated temperatures, the lipid micropellets lost their smooth surface structures because of polymorphic transformations.

Novel oral controlled release microspheres using polyglycerolesters of fatty acids and hydrogenated cottonseed oil (HCSO), stearic acid, stearyl alcohol, or glycerol monostearate as carriers were prepared by spray chilling using a rotating disc (68). The drug release was related to the hydrophobicity of the wax; the release rate decreased in the following order: stearyl alcohol > stearic acid > glycerol monostearate > carnauba wax > hydrogenated cottonseed oil. Adding increasing amounts of lactose to HCSO increased the drug release as a result of the leaching of lactose.

A new atomizer operating with ultrasonic energy was used as an alternative to traditional atomizers to prepare wax microparticles by spray congealing (69).

WORLD HEALTH ORGANIZATION (WHO) CONTINUES GLOBAL HARMONIZATION OF REQUIREMENTS FOR MEDICINAL PRODUCTS

Juhana E. Idänpään-Heikkilä

*Council for International Organizations of Medical Sciences,
WHO, Geneva, Switzerland*

INTRODUCTION

The World Health Organization (WHO) is an intergovernmental specialized agency of the United Nations with 193 member states. Regarding pharmaceutical and biological products, WHO has the global mandate to develop, establish, and promote quality, safety, and efficacy standards and codes of good practices for all medicinal products. Vigorous harmonization of quality, safety, efficacy, and nomenclature requirements on a worldwide basis has continued in 1998–2000 as the explicit responsibility of WHO. The content of the constitutional mandate, expertise involved, working practices and rules, consultative processes, and role of the governing bodies regarding WHO's normative work was described in detail in the *Encyclopedia of Pharmaceutical Technology*, Vol. 18 (1). This review gives an update on ongoing harmonization activities since 1998 and outlines the new harmonization initiatives.

International Nonproprietary Names (INNs)

The International Nonproprietary Names (INNs) identifies pharmaceutical substances by unique, globally recognized names. A single internationally recognized name for an active drug substance is a starting point for its pharmacopeial monograph, safe prescribing and dispensing, and easy communication among scientists and health professionals worldwide. The INN is for common use without restrictions (except as a trademark); it is distinctive in sound and spelling and not too long. In 1998–1999, WHO published more than 270 new INNs in its quarterly publication, *WHO Drug Information* (2) and issued a revised *Guidelines on the Use of International Nonproprietary Names (INN) for Pharmaceutical Substances* (3). The revision of the procedure included the introduction of a service fee, improvements in Procedures to raise objections to proposed INNs, and the replacement of a recommended INN.

Naming the biotechnology-derived substances and products received increasing attention. Prevention of INNs from using trademarks has now been strengthened in collaboration with the World Intellectual Property Organization (WIPO). A new point of collaboration was the protection of INNs against misuse of Internet domain names (4).

International Pharmacopoeia—50 Years Old

Publication of the International Pharmacopoeia has continued now for 50 years. Its role has been to fulfill a need in developing countries where use of less technically advanced tests using simple instrumentation is common practice for specific substances and preparations. Publishing monographs for finished products has also been useful. In 1999, the Expert Committee recommended that less-advanced methods should be developed in parallel with modern analytical techniques because in some developing countries, more sophisticated methods could be useful (4). Volume 5 of the International Pharmacopoeia is in print. WHO has completed monographs for several antimalarials including artemisin derivatives. Basic tests for pharmaceutical substances, medicinal plant materials, and dosage forms (including 345 tests for substances, 208 for dosage forms, and four for plant materials) were published in 1998 (5). The 69 International Infrared Reference Spectra (IIRS) have been made available from the WHO Collaborating Centre for Chemical Reference Substances (Kungens Kurva, Sweden). The list of reference substances and infrared reference spectra is updated regularly and is now available on the World Wide Web (<http://www.who.int/dmp/irintro.htm>).

A revised guideline on Good Practices for National Pharmaceutical Control Laboratories (GPCL) was published in 1999. It takes into account guidances from ISO 17025, EN 45001, and OECD–GLP and

recommendations published by the Pharmaceutical Inspection Convention (PIC) (4).

WHO GMP and Quality Assurance

In 1998, WHO began a special project to assist in implementing of GMP in member states with limited resources. Countries interested in upgrading their manufacturing have been identified, and training material on basic GMP principles has been prepared together with training modules for advanced GMP topics and inspections. Several regional training workshops for trainers in GMP have been organized, together with missions to concerned countries (4).

The following guidelines have been completed: GMP for Sterile Pharmaceutical Products, Guideline on Pre-Approval Inspection (before granting marketing authorization), Quality System for National GMP Inspectorate, and General Aspects of Packaging Pharmaceuticals (4).

In 1999, WHO published a report on the control and safe trade of starting materials for pharmaceutical products in English, French, Spanish, Russian, Chinese, and Arabic, based on recommendations from a meeting of experts in Geneva in May 1998 (6). The meeting was inspired by several recent incidents of contamination with highly toxic solvent diethylene glycol.

Because of their increasing use worldwide, plant materials used in over-the-counter preparations, home remedies, or as raw materials for pharmaceutical preparations are receiving more and more attention. In 1998, WHO published a book, *Quality Control Methods for Medicinal Plant Materials* to fulfill the needs of quality control laboratories and to provide a basis for the development of national standards (7).

A compendium of WHO guidelines and related materials entitled *Quality Assurance of Pharmaceuticals*, Volume 1, was published (8) and the next volume is in print.

Counterfeit drugs

In 1999, WHO published guidelines on the detection and prevention of counterfeit and substandard products (9). Vigilance and reporting of counterfeit products to WHO were enhanced by setting up a liaison officer network among drug regulatory authorities and WHO.

The WHO Certification Scheme

The WHO Certification Scheme on the Quality of Pharmaceutical Products Moving in International Commerce (1) was used in increasing the number of countries as a model instrument to exchange information among authorities in importing and exporting countries. In 1999,

WHO completed a model certificate of analysis to be used for trade of starting materials intended for drug manufacturing, and manufacturers of pharmaceutical substances, excipients, and medicinal products (4).

Comparator product system for equivalence testing

The use of generic pharmaceutical products has increased in many countries. Consequently, drug regulatory authorities are increasingly involved in the assessment of the scientific documentation submitted for marketing approval of generic medicinal products. WHO has stated that the quality, safety, and efficacy of a generic product must comply with the same requirements applied to the innovator (10). Consequently, the therapeutic equivalency and interchangeability with the innovator must be proven with valid comparative in vivo bioequivalence studies. To assist both manufacturers and drug regulators in this, WHO has developed a list of international comparator products. The information on comparator products was collected first from drug regulatory agencies, and a provisional list of candidate products was consulted with the innovator companies concerned. The companies were requested to designate the market and trademark that best represented the quality, manufacturing, and labeling of the product. The current list thus far contains 147 products from the WHO Model List of Essential Drugs, complemented with detailed instructions for use and a decision tree for special situations (11). The list will be updated periodically by WHO.

The WHO Model List of Essential Drugs

The Model List of Essential Drugs was created in 1975, and the most recent assessment and updating of the list took place in 1997 and 1999 (12,13). The following additions to the list were made including aciclovir for use in herpes infections; amoxicillin + clavulanic acid for the treatment of infections resistant to the production of β -lactamase; dextrometorphan for the treatment of cough; ephedrine for treatment of hypotension in spinal anesthesia during delivery; imipenem + cilastatin for the treatment of *Pseudomonas*; ipratropium bromide for the treatment of asthma; metformin for the treatment of noninsulin-dependent diabetes; triclabendazole for the treatment of liver and lung flukes; and nevirapine and zidovudine to reduce or prevent mother-to-child transmission of HIV infection. The value of lipid-lowering agents was discussed; however, because of their high costs, they were not included in the list, with a recommendation that each country make its own decisions for use in high-risk patient populations (12).

Sale and promotion of medical products on the internet

The Internet is a rapidly expanding medium that has many uses and great potential for disseminating and obtaining information regarding a variety of subjects such as new treatments, institutions offering care, and medical products available. Individuals can get this information more quickly and conveniently than in traditional ways, such as in medical journals and textbooks. Organizations, pharmaceutical companies, and individuals post and exchange information about their aims, activities, or products and sometimes offer to sell their products, including medical products. However, have the products been approved for marketing? Are they safe, effective, properly labeled, and of good quality? Reported cases show that dangerous, harmful, unreliable, low-quality, substandard, fake, counterfeit, and mislabeled products have been available on the Internet (14).

The World Health Assembly (the annual summit of Ministries of Health of 193 member states of WHO) recognized in May 1997 the increasing use of electronic communication by the general public to shop and gather information on health education, diseases, treatments, and medical products (15). The Assembly was concerned about reported cases of inappropriate use of the Internet, which had caused a potential hazard for public health, and decided to convene a WHO ad hoc working group to formulate recommendations for action. The working group met in September 1997 in Geneva and consisted of representatives of health and drug regulatory authorities, consumer groups, professional associations, the pharmaceutical industry, experts in legal and ethical matters, marketing, and other interested parties. The group reviewed the situation and made several recommendations regarding cross-border advertising, promotion, and sale of medical products. Based on these recommendations, in May 1998 (16) the World Health Assembly urged all member states to review existing legislation, regulations, and guidelines to ensure that they are applicable and adequate to cover the promotion and sale of medical products over the Internet. Member states were asked to set up monitoring and surveillance systems for the Internet. Collaboration was recommended among countries to identify difficult cases and disseminate information through WHO. The availability of scientific, validated information to consumers by competent health authorities was determined to be necessary.

The Assembly appealed to the pharmaceutical industry, health professional and consumer organizations, and other interested parties to promote the formulation and use of good information practices consistent with the principles

of the WHO Ethical Criteria for Medicinal Drug Promotion; monitor and report problem cases and aspects of cross-border advertising, promotion, and sale of medical products using the Internet; and maintain legal and ethical standards in these activities.

WHO was requested to encourage the international community to formulate self-regulatory guidelines for good information practices and to develop a model guide for member states. The guide should educate and instruct people using the Internet on how to best obtain reliable, independent, and compatible information on medical products through this medium. The WHO model guide, *Medical Products and the Internet*, was published in 1999 (17).

Biologicals

WHO's normative work for biological substances used in medicinal products, including vaccines, blood products, and diagnostic procedures, has resulted in a number of globally applicable specifications, guidelines, and guiding principles. In 1999, WHO published guidelines for the production and quality control of synthetic peptide vaccines for human use to ensure their consistent safety and efficacy (18). The guidelines address control of starting materials including background data on the synthesis of the peptide of interest and control of the manufacturing process and the final product. WHO requirements for tick-borne encephalitis vaccine (inactivated) were formulated to take into account current manufacturing practices and control procedures in place and to give guidance on how these practices and procedures could be updated (18). Requirements for hepatitis B vaccines made by recombinant DNA techniques have been amended to reflect recent developments in assay methodology, as well as for specifications for *Haemophilus* type b conjugate vaccines. Under development were guidelines for standardization and calibration of cytokine immunoassays, and requirements for tetravalent dengue vaccine (live) and oral poliomyelitis vaccine (18).

In 1999, WHO published requirements for production and control of *Haemophilus influenzae* type b (Hib) conjugate vaccine and the acellular pertussis component of monovalent or combined vaccines. The requirements for oral polio vaccine (OPV) were also revised in 1999, with several additions. WHO published new and replacement International Standards and Reference Materials covering a wide range of products (19).

WHO, ICH, and Regional Harmonization

The role of WHO as an observer of the ICH and its contribution as a global, intergovernmental organization to

tripartite ICH activities involving 17 WHO member states have been described in detail (1).

With strong support from WHO, the ICH Steering Committee decided in 1997 to accept the participation of experts from the International Generic Pharmaceutical Alliance (IGPA) and the World Self-Medication Industry (WSMI) in the designated expert working groups (20). This was a first step toward a more comprehensive harmonization procedure. Since 1998, WHO participated as an observer in drafting a guideline for good manufacturing practices for active pharmaceutical ingredients based on preliminary work by the Pharmaceutical Inspection Co-operation Scheme (PIC/S). Australia, China, and India, known for their extensive production of pharmaceutical substances and excipients, were invited to participate in this exercise. The draft guideline is still in development and was an ICH step 2 document in February 2000.

Because Common Technical Document (CTD) (content and format of a new drug application) was accepted as a new ICH topic in 1998, WHO asked a WHO regional adviser for pharmaceuticals from each of the six WHO regions to coordinate among ICH CTD working groups and drug regulatory authorities WHO regions (20). This is an important development because the CTD will undoubtedly have an impact on new drug applications in non-ICH countries and industries. The CTD expert working groups succeeded in 1999 to sign off as step 2 document tables of contents for all three sections of the CTD, namely quality, safety, and efficacy. Significant work remains to be done, and the progress has been slowest in the quality section.

In 1999, the ICH began a major revision of its existing stability testing guideline. To make this guideline practical and useful for all countries, WHO suggested that it should address not only new molecular entities and associated drug products but also stability testing of generic pharmaceutical products in its new revised form. Furthermore, WHO proposed that it should address, in addition to its current coverage of only climatic zones I and II, the remaining critical climatic zones, namely zone III (hot/dry) and zone IV (hot/humid). The WHO guidelines on stability testing of pharmaceutical products containing well-established (generic) drug substances in conventional dosage forms cover all four climatic zones (21).

X-RAY POWDER DIFFRACTOMETRY^a

Raj Suryanarayanan

University of Minnesota, Minneapolis, Minnesota, U.S.A.

Suneel Rastogi

Forest Laboratories, Inc., Inwood, New York, U.S.A.

INTRODUCTION

X-rays are electromagnetic radiation lying between ultraviolet and gamma rays in the electromagnetic spectrum. The wavelength of the X-ray region is considered to be between 0.01 and 100 Å (1).

There are two broad applications of X-rays in the characterization of materials: (i) X-ray spectrometry and (ii) X-ray diffractometry. The former technique is used for chemical analysis and has found only limited use in the characterization of pharmaceuticals. On the other hand, X-ray diffractometry, by providing a means for the study of the structure of crystalline materials, is extensively used to characterize pharmaceutical solids. There are two principal applications of X-ray diffractometry. X-ray crystallography is concerned with the structure determination of crystalline phases. Single crystals are usually used for this purpose. On the other hand, in X-ray powder diffractometry, the sample is usually in the form of a powder. X-ray powder diffractometry is recognized as a powerful technique for the identification of crystalline phases. The technique can also be used for the quantitative analyses of solids. This article will be restricted to the principles and applications of X-ray powder diffractometry (XRD) in the characterization of pharmaceutical solids.

Diffraction is a scattering phenomenon. When X-rays are incident on crystalline solids, they are scattered in all directions. In some of these directions, the scattered beams are completely in phase and reinforce one another to form the diffracted beams (1, 2). The Bragg law describes the conditions under which this would occur. It is assumed that a perfectly parallel and monochromatic X-ray beam,

of wavelength λ , is incident on a crystalline sample at an angle θ . Diffraction will occur if:

$$n\lambda = 2d \sin \theta \quad (1)$$

where d = distance between the successive planes in the crystal lattice, expressed in Å, and n = order of reflection (an integer).

X-ray patterns can be obtained using either a powder diffractometer or a camera. Currently, diffractometers find widespread use in the analysis of pharmaceutical solids. The technique is usually nondestructive in nature. The theory and operation of powder diffractometers is outside the scope of this discussion, but these topics have received excellent coverage elsewhere (1–4). Instead, the discussion will be restricted to the applications of X-ray powder diffractometry (XRD) in the analysis of pharmaceutical solids. The United States Pharmacopeia provides a brief but comprehensive introduction to X-ray diffractometry (5). The use of XRD in the physical characterization of pharmaceutical solids (6) and in the characterization of controlled release delivery systems have been discussed earlier (7).

QUALITATIVE ANALYSIS

Since the X-ray diffraction pattern of every crystalline form of a compound is unique, the technique is widely used for the identification and characterization of solid phases. XRD is the technique of choice to identify different polymorphic forms of a compound (Fig. 1) (8). It can also be used to identify the solvated and unsolvated (anhydrous) forms of a compound, provided their lattice structures are different. The technique can also reveal differences in the crystallinity of compounds. The XRD pattern of an amorphous (noncrystalline) compound will consist of one or more broad diffuse halos (see Fig. 2; upper panel) (9).

The United States Pharmacopeia contains the XRD patterns of two anhydrous forms (Form 1 and Form 2) of

^aSome parts of this article have been reproduced from the chapter, "X-ray Powder Diffractometry," written by R. Suryanarayanan in "Physical Characterization of Pharmaceutical Solids," edited by H. Brittain. This was Vol. 70 of *Drugs and Pharmaceutical Sciences*, Editor: J. Swarbrick, Marcel Dekker, Inc., New York, 1995.

Fig. 1 X-ray powder diffraction (XRD) patterns of the different solid forms of AG337. (From Ref. 8.)

ampicillin, ampicillin trihydrate and amorphous anhydrous ampicillin (5). The powder patterns of these four solid phases reveal pronounced differences, which can form the basis of their identification.

XRD was a powerful tool for the characterization of the different solid phases of AG337 (a 5-substituted quinazolinone; dihydrochloride salt). In addition to several polymorphic forms of the anhydrate ($C_{14}H_{12}N_4OS \cdot 2HCl$), the compound existed as a hemihydrate ($C_{14}H_{12}N_4OS \cdot 2HCl \cdot 0.5H_2O$), a monohydrate ($C_{14}H_{12}N_4OS \cdot 2HCl \cdot H_2O$), and a dihydrate ($C_{14}H_{12}N_4OS \cdot 2HCl \cdot 2H_2O$) (8). The hemihydrate, the dihydrate, and one of the polymorphic forms of the anhydrate (I_8) had identical lattice structures (Fig. 1).

While the amorphous and crystalline solid forms of sucrose can be readily distinguished by XRD (Fig. 2, upper panel), the technique is also capable of revealing the presence of small amounts of crystalline sucrose in the presence of amorphous sucrose (9). This is evident from the XRD patterns of physical mixtures of amorphous and crystalline sucrose wherein the crystalline sucrose content ranged between 1 and 5 wt% (Fig. 2, lower panel).

Six crystalline solid phases of fluprednisolone and an amorphous phase were characterized using XRD, IR spectroscopy, and differential scanning calorimetry (10). Three of these six crystalline phases were anhydrous, two were monohydrates, and one was a tert-butylamine

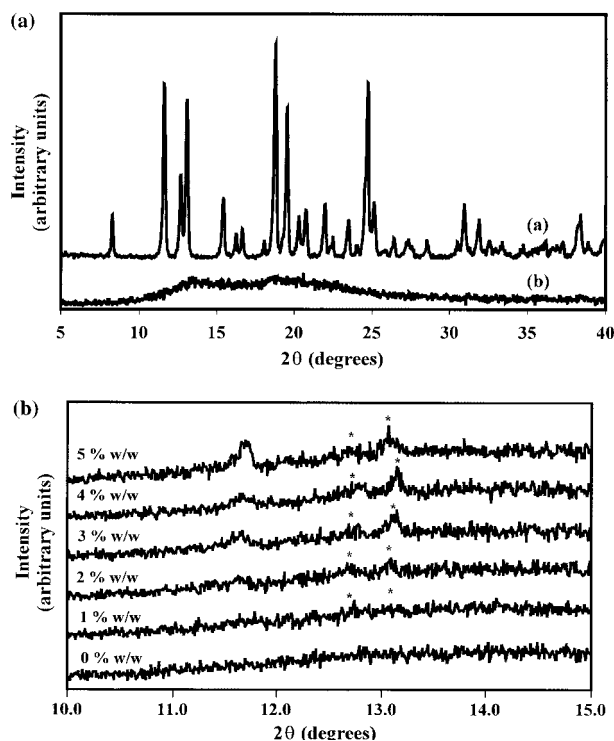

Fig. 2 Upper panel: XRD patterns of (a) crystalline and (b) amorphous sucrose. Lower panel: XRD patterns of the physical mixtures of crystalline and amorphous sucrose. The sucrose content ranged between 0 and 5 wt%. The 12.7 and 13.1°2θ peaks were used for the quantitative analyses. (Bottom panel reproduced from Ref. 9.)

disolvate. The differences in the powder patterns of the phases were readily evident. This study demonstrated the unique ability of XRD for the identification of (a) an anhydrous compound existing in both crystalline and amorphous states, (b) different polymorphic forms of the anhydrate, (c) the existence of solvates, where the solvent of crystallization is water (hydrate) or an organic solvent (in this case, tert-butylamine), and (d) polymorphism in the hydrate.

Reference Diffraction Patterns

The International Centre for Diffraction Data (ICDD, Newtown Square, PA) maintains a collection of single-phase X-ray powder patterns (11). There are separate listings of inorganic and organic compounds. The X-ray diffraction data of ibuprofen, as a representative example is given here (Table 1).

The card pattern contains the Powder Diffraction File (PDF) number (Region 1); quality mark of the data (Region 2); the chemical formula and the specimen name

There are also several indicators of the quality of the data. The highest quality data are given*. To qualify for this mark, the chemistry of the compound must be well characterized. The intensities of the X-ray lines must be measured objectively and instrumentally and there must be no unindexed, space group extinct or impurity lines. Lines with d -spacings of ≤ 2.50 Å must retain at least three significant digits after the decimal point. To qualify for the “i” mark, there can be a maximum of two unindexed, space

group extinct or impurity lines provided none of these belong to the strongest eight. Again there must be no serious systematic errors and lines with d -spacings ≤ 2.00 Å must retain at least three significant digits after the decimal point. If the data are of low precision or if the data are due to a poorly characterized or multiphase system, an “O” mark is assigned. Patterns that do not meet the criteria for “*,” “i,” or “O” are left blank. When the powder pattern is calculated from structural parameters, the pattern is marked “C.” Extensive details about the quality mark guidelines can be found in ICDD publications (12).

Another important database for pharmaceuticals is the Cambridge Structural Database (CSD). Maintained by the Cambridge Crystallographic Data Centre, CSD is a compilation of single-phase data containing structural information including unit cell parameters, crystal system, and space group. The structural information can be used to

calculate powder diffraction patterns. The ICDD and the Cambridge Crystallographic Data Centre have a cooperative program. This allows the ICDD to calculate powder patterns for inclusion in the Powder Diffraction File, from the data recorded in the CSD.

Phase Identification in Solid Dosage Forms

In addition to the active ingredient, solid dosage forms usually contain one or more excipients. In such powder mixtures, each crystalline phase produces its pattern independently of the other constituents in the mixture. Thus, the unique advantage of XRD is that it combines absolute specificity with a high degree of accuracy. Shell pioneered the use of XRD in the characterization of pharmaceutical dosage forms (13). The recent advances in instrumentation and software have substantially enhanced the utility of the technique. XRD was used to simultaneously identify the three active ingredients, acetaminophen, aspirin, and caffeine, in a commercially available tablet formulation (Excedrin®). The three active ingredients together constituted 83 wt% of the formulation (14). The XRD pattern contained numerous peaks in the angular range of 7–37° 2 θ (Fig. 3d). In an effort to identify the components in the dosage form, the XRD patterns of acetaminophen, aspirin, and caffeine were obtained (Fig. 3a–c). Acetaminophen could be readily identified by two unique lines with *d*-spacings of 6.48 and 4.92 Å (2 θ values of 13.65 and 18.00°, respectively). At these 2 θ values, the XRD patterns of aspirin and caffeine contained no peaks. Similarly, aspirin could be readily identified by two unique lines with *d*-spacings of 11.54 and

3.95 Å (2 θ values of 7.65 and 22.45°, respectively). Caffeine had an intense line with a *d*-spacing of 7.55 Å (2 θ value of 11.70°) and two intense lines with *d*-spacings of 3.39 and 3.31 Å (2 θ values of 26.25 and 26.85°, respectively). Since at these 2 θ values, peaks due to aspirin and acetaminophen occurred, unambiguous identification of caffeine was not possible. An added complication was that caffeine constituted only 8.9 wt% of the formulation.

In order to identify caffeine, the XRD patterns of acetaminophen and aspirin were selectively subtracted from the XRD pattern of the formulation. The details of the pattern subtraction procedure are described in the literature (14). When the subtracted profile (Fig. 4a) was compared with that of caffeine (Fig. 4b), the high intensity peaks of caffeine at 11.70, 26.25, and 26.85° 2 θ were readily discernible. However, an amorphous halo was observed over the angular range of 18–23° 2 θ . The formulation contained numerous excipients including microcrystalline cellulose, hydroxypropyl methylcellulose, and hydroxypropyl cellulose. The XRD pattern of microcrystalline cellulose exhibited a broad halo over the angular range of 18–25° 2 θ (Fig. 5c). While amorphous halos were also observed in the XRD patterns of hydroxypropyl methylcellulose (Fig. 5b) and hydroxypropyl cellulose (Fig. 5a), their angular range did not match that of the formulation (Fig. 5d). Therefore, microcrystalline cellulose is likely to be the major contributor to the observed halo. Thus, XRD not only permitted simultaneous identification of all the active ingredients in the dosage form, but it also provided information about the excipients in the formulation.

The authors also evaluated the sensitivity of the method, using chlordiazepoxide HCl (hereafter referred to

Fig. 3 (a) The XRD pattern of acetaminophen powder. (b) The XRD pattern of aspirin powder. (c) The XRD pattern of caffeine powder. (d) The XRD pattern of a powdered tablet formulation containing acetaminophen, aspirin, and caffeine (Excedrin®). (From Ref. 14.)

as chlordiazepoxide) as the model compound (14). While chlordiazepoxide was crystalline (Fig. 6a), microcrystalline cellulose exhibited a broad amorphous halo (Fig. 6c). Identifying chlordiazepoxide was no problem so long as its weight fraction was ≥ 0.10 . When the drug weight fraction was decreased to 0.05, its presence was not readily discernible (Fig. 6b). Using the pattern subtraction technique, the XRD pattern of microcrystalline

Fig. 6 (a) The XRD pattern of chlordiazepoxide hydrochloride powder. (b) The XRD pattern of a powder mixture of chlordiazepoxide hydrochloride (5 wt%) and microcrystalline cellulose (95 wt%). (c) The XRD pattern of microcrystalline cellulose powder. cellulose was subtracted from the XRD pattern of the drug-microcrystalline cellulose mixture (Fig. 6d). This permitted ready identification of chlordiazepoxide (compare Fig. 6d with Fig. 6a).

Phase Transitions Induced During Processing

The components of a dosage form, both active ingredients and excipients, can undergo a variety of physical transformations during pharmaceutical processing and storage. These include polymorphic transformations, alterations in crystallinity, and changes in the state and degree of hydration. XRD is well-suited for analyses of such transformations, provided the analytes are crystalline. In most cases, the dosage forms can be analyzed directly with minimal or no sample pretreatment. There is no need to extract the active ingredient from the dosage form, since it can be usually characterized in presence of the excipient(s). The technique will permit simultaneous identification and quantification of more than one active ingredient in formulations. Finally, XRD can provide quantitative information about the degree of crystallinity.

When theophylline monohydrate was dehydrated, it formed a metastable anhydrous phase, which then transformed to the stable anhydrate (15). The XRD patterns of the two anhydrate phases and the monohydrate were sufficiently different so that all three of them could be simultaneously identified in a sample (Fig. 7; upper panel). Anhydrous theophylline was granulated with an aqueous solution of PVP. During the wet-massing stage, the anhydrate transformed to the monohydrate. When the granules were dried, there was dehydration resulting in the formation of the metastable anhydrate, which then transformed to the stable anhydrate. All three phases were simultaneously monitored by XRD (Fig. 7; lower panel).

DEGREE OF CRYSTALLINITY

Solids may be either crystalline or noncrystalline. The crystalline state is characterized by a perfectly ordered lattice and the noncrystalline (amorphous) state is characterized by a disordered lattice. These represent two extremes of lattice order and intermediate states are possible. The term degree of crystallinity is useful in attempts to quantify these intermediate states of lattice order.

XRD is widely used to determine the degree of crystallinity of pharmaceuticals. The procedure developed by Hermans and Weidinger (16) is based on three assumptions. First, it must be possible to demarcate and

Fig. 7 Upper panel: XRD patterns of theophylline phases. M, A, and A* refer to theophylline monohydrate, stable anhydrous theophylline, and metastable anhydrous theophylline respectively. Lower panel: Phase transitions during the drying of theophylline granules. PVP was the granulating agent. The integrated intensities of the 8.9, 9.4, and 7.0° 2θ peaks unique to M, A*, and A respectively were simultaneously monitored as a function of the drying time. (From Ref. 15.)

measure the crystalline intensity (I_c) and amorphous intensity (I_a) from the powder pattern. Usually, the integrated line intensity (area under the curve), rather than the peak intensity (peak height), is measured. Second, there is a proportionality between the experimentally measured crystalline intensity and the crystalline fraction (x_c) in the sample. Finally, a proportionality exists between the experimentally measured amorphous intensity and the amorphous fraction (x_a) in the sample. The degree of crystallinity (or percent crystallinity), x_{cr} , is given by the expression,

$$x_{cr} = \frac{I_c 100}{I_c + \frac{qI_a}{p}} \quad (2)$$

where p and q are proportionality constants. The values of I_a and I_c can be determined for samples of varying degrees of crystallinity. A plot of the measured values of I_a against those of I_c will result in a straight line, and

the intercepts on the y- and x-axes will provide the intensity values of the 100% amorphous and 100% crystalline materials, respectively. This method was used by Nakai et al. (17) to estimate the degree of crystallinity of lactose that had been milled for various time periods (Fig. 8). If the value of (q/p) is known, the degree of crystallinity of an unknown sample can be calculated from the experimentally determined values of I_c and I_a . The degree of crystallinity of microcrystalline cellulose and digoxin milled for various time periods were also determined (18, 19). The problems and limitations of this method have been discussed in the literature (6).

A number of drugs and excipients exist in the amorphous state. However, the physical instability of amorphous compounds can lead to their crystallization resulting in partially crystalline materials. In recent years, several techniques have been developed to quantify low levels of an amorphous compound in presence of its crystalline counterpart. Using sucrose as a model compound, an XRD method was developed to detect and to quantify crystalline sucrose when it occurred as a mixture with amorphous sucrose (9). The XRD patterns of amorphous and crystalline sucrose were presented earlier (Fig. 2). Standards consisting of amorphous and crystalline sucrose were prepared wherein the crystalline sucrose content ranged between 1 and 5 wt%. The sum of the background subtracted integrated intensities of the 12.7° 2θ (6.94 Å) and 13.1° 2θ (6.73 Å) peaks of sucrose

Fig. 8 A plot of the integrated amorphous intensity (I_{am}) as a function of the integrated crystalline intensity (I_c) for lactose samples milled for various time periods. (From Ref.17.)

Fig. 9 Plot of the sum of the intensities of the 12.7 and 13.1° 2θ peaks as a function of the weight percent of crystalline sucrose in mixtures of amorphous and crystalline sucrose. (From Ref. 9.)

(these peaks have been marked with an asterisk in Fig. 2) were linearly related to the weight percent of sucrose (Fig. 9).

The limits of detection and quantitation of crystalline sucrose were determined to be 0.9 and 1.8 wt% respectively. Water sorption and FT-Raman spectroscopy also appear to be very sensitive with detection possible down to levels of 1 wt% (20, 21).

PHASE QUANTIFICATION (QUANTITATIVE ANALYSIS)

The Direct Method (No Internal Standard)

Alexander and Klug developed the theoretical basis of the quantitative analyses of powder mixtures (3). Although a powder mixture may be composed of several components, it can be regarded as being composed of just two components: Component 1 (which is the unknown) and the sum of the other components (which is designated as the matrix). The relationship between the intensity of peak *i* of the unknown component (I_{i1}) and its weight fraction (x_1) in the mixture is given by the equation:

$$I_{i1} = \frac{Kx_1}{\rho_1[x_1(\mu_1^* - \mu_M^*) + \mu_M^*]} \quad (3)$$

where K is a constant, ρ_1 is the density of Component 1, and μ_1^* and μ_M^* are the mass attenuation coefficients of Components 1 and the matrix respectively. The mass attenuation coefficient of a substance is the weighted average of the mass attenuation coefficients of its constituent elements.

Let us first consider a two-component mixture, where $\mu_1^* \neq \mu_M^*$. One example is a mixture of the anhydrous

and hydrated forms of a compound. It is first necessary to determine the intensity of peak *i* of a sample consisting of only the analyte $[(I_{i1})_0]$. Next, Equation (3) is modified so that the relative intensity of the XRD peak of Component 1 [expressed as $(I_{i1})/(I_{i1})_0$] is expressed as:

$$\frac{I_{i1}}{(I_{i1})_0} = \frac{x_1\mu_1^*}{x_1(\mu_1^* - \mu_M^*) + \mu_M^*} \quad (4)$$

It is possible to calculate the mass attenuation coefficients of the analyte and the matrix based on their chemical compositions (2). This enables the calculation of the relative intensity $[I_{i1}/(I_{i1})_0]$ as a function of the weight fraction of the analyte in the mixture and thus generate a theoretical curve. This eliminates the need for the preparation of experimental standard curves. An added advantage of this approach is that there is no requirement of an internal standard.

This approach was used to determine the weight fractions of anhydrous carbamazepine and carbamazepine dihydrate when they occurred as mixtures (22). Based on the mass attenuation coefficients of the anhydrate and the dihydrate, the intensity ratios $[I_{i1}/(I_{i1})_0]$ were calculated as a function of the anhydrate content in the mixture (the line in Fig. 10). These were in good agreement with the experimentally obtained values of $[I_{i1}/(I_{i1})_0]$.

A simpler system is a two component mixture, where $\mu_1^* = \mu_M^*$. This occurs when the analyte and the matrix have the same molecular formula, as in polymorphic mixtures. In such cases, Equation (4) reduces to:

$$\frac{I_{i1}}{(I_{i1})_0} = x_1 \quad (5)$$

Therefore a plot of the relative intensity as a function of the analyte weight fraction would be linear. This approach was used to determine the weight fractions of anhydrous α -carbamazepine and β -carbamazepine when they occurred as mixtures (23). While studying the polymorphism of 1,2-dihydro-6-neopentyl-2-oxonicotinic acid, Chao and Vail (24) used XRD to quantify Form I in mixtures of Forms I and II. They estimated that Form I levels as low as 0.5 wt% can be determined by this technique. Similarly the α -inosine content in a mixture consisting of α - and β -inosine was achieved with a detection limit of 0.4 wt% for α -inosine (25).

Internal Standard Method

In this method, an internal standard is added, and its weight fraction is maintained constant in all the mixtures. This method was used to simultaneously quantify the S(+)-enantiomer and the racemic compound of ibuprofen (26).

Fig. 10 The relative intensity of the 6.78 Å line of anhydrous carbamazepine (β -form) as a function of its weight fraction in binary mixtures of anhydrous carbamazepine (β -form) and carbamazepine dihydrate. The line is based on theoretical values, while the data points are experimental measurements. (From Ref. 22.)

Selection of Internal Standard

Success in quantitative XRD may hinge on the selection of an appropriate Internal Standard. The following properties are desired in an internal standard (13). (i) The compound must have high crystal symmetry so that strong, but few, diffraction peaks are produced. (ii) The high-intensity lines in the analyte and the internal standard that are to be used for quantitative purposes should not overlap with one another, but they should be close to each other. (iii) The density of the internal standard should be close to that of the system ingredients so that homogeneous mixtures can be prepared for analysis. (iv) The internal standard must be chemically stable in the experimental system. When dealing with organic pharmaceutical systems, an organic internal standard is preferred. Since the XRD patterns of organic compounds usually contain numerous lines, it might not be possible to identify lines unique to the analyte and the internal standard that are completely separated from one another. Therefore, inorganic compounds such as corundum (α - Al_2O_3), silicon, lithium fluoride, and zinc oxide are often used as internal standards. Methenamine, an organic compound, has several of the properties desired in an internal standard (13). However, it has not found widespread use in the analyses of pharmaceuticals.

Whole Powder Pattern Analyses

In the pharmaceutical community, quantitative analyses has conventionally been based on the intensity of a characteristic peak of the analyte. It is now recognized that phase quantification will be more accurate if it is based on the *entire* powder pattern (27, 28). This forms the basis for the whole-powder-pattern analyses method developed in the last few decades. Of the available methods, the Rietveld method is deemed the most powerful since it is based on structural parameters. This is a whole-pattern fitting least-squares refinement technique that has also been extensively used for crystal structure refinement and to determine the size and strain of crystallites.

Simultaneous quantitative analyses, of complex pharmaceutical mixtures, has been accomplished by the Rietveld method (29). Using lithium fluoride as an internal standard, mixtures consisting of anhydrous β -carbamazepine, anhydrous α -carbamazepine, and carbamazepine dihydrate were subjected to quantitative analyses (Table 2). When the analyte concentration was high ($\geq 20\%$), the method was accurate, with a relative error $< \pm 5\%$. However, when the analyte concentration was low ($< 5\%$), the method lacked accuracy.

NONAMBIENT XRD

Conventionally, XRD patterns are obtained at room temperature under ambient conditions. Variable temperature XRD is a technique where XRD patterns are obtained while the sample is subjected to a controlled temperature program. It is also possible to control the environment and maintain the sample under the desired relative humidity. Recent advances in commercially available instrumentation have greatly facilitated the study of pharmaceutical systems under nonambient conditions. Experiments can be carried out both at elevated temperatures and under subambient conditions.

High Temperature XRD

In the characterization of pharmaceutical systems, high temperature XRD has been used extensively. The phase transitions of theophylline monohydrate were discussed earlier in the section dealing with Phase Transitions Induced During Processing (Fig. 7). High temperature XRD was used to investigate the dehydration of theophylline monohydrate (Fig. 11). This technique revealed that dehydration resulted in a metastable

anhydrous phase, which then transformed to the stable anhydrate (30). Theophylline has been in widespread use for many years and its solid-state properties have been the subject of numerous investigations. Without high temperature XRD, it is unlikely that this metastable phase would have been identified.

Kinetics of Solid-State Reactions

Solid-state reactions in pharmaceuticals can be broadly classified into chemical decompositions and physical transformations. The chemical decomposition of drugs has received adequate attention in the pharmaceutical literature. The active ingredient in a solid dosage form can also undergo a variety of physical transformations including polymorphic transitions, alterations in degree of crystallinity, and alterations in degree of solvation. These transformations can affect pharmaceutically important properties such as solubility, stability, powder flow, and tableting behavior, which ultimately can cause variations in the performance of the product. There are strict pharmacopeial standards, which govern not only the chemical purity of drugs and excipients, but also the drug content in dosage forms. On the other hand, very few compounds have pharmacopeial standards that govern their physical form. However, it is increasingly recognized that the physical form of a compound and physical transformations in a dosage form can profoundly affect product performance. An added complication is that

conventional analytical techniques such as HPLC, which are used for monitoring chemical decomposition reactions are unsuitable to monitor solid-state physical transformations. This is because of their inability to distinguish between the different solid forms of a compound. Both chemical decomposition as well as physical transitions can occur simultaneously during the processing or storage of solid formulations. Therefore, it would be ideal if an analytical technique can simultaneously monitor both types of transformations. XRD is one such technique.

Conventionally, thermoanalytical techniques, specifically differential scanning calorimetry and thermogravimetric analysis, have been used to investigate the kinetics of solid-state reactions. These techniques have several limitations. They do not unambiguously identify crystalline phases and are incapable of providing quantitative information about the degree of crystallinity. Intermediate phases, if formed, may not be readily identified. The techniques may therefore be unsuitable for discerning the reaction mechanism. When two or more gaseous products are simultaneously evolved, thermal analysis alone is not very helpful in the study of reaction kinetics. In such cases, thermal analysis should be used in conjunction with other techniques for evolved gas analysis (e.g. infrared spectroscopy, mass spectroscopy, or gas chromatography). It is often realized that solid-state reactions take place through complex mechanisms involving intermediates and the same end product is obtained through multiple pathways. In such cases, thermoanalytical

Fig. 11 High temperature XRD of theophylline monohydrate. XRD patterns were obtained at the temperatures indicated in the figure. The “*,” “+,” and “O” marks indicate peaks unique to metastable anhydrous theophylline (referred to as A* in Fig. 7), stable anhydrous theophylline (A in Fig. 7), and theophylline monohydrate (M in Fig. 7) respectively. (Adapted from Ref. 30.)

techniques yield complex profiles because of overlapping thermal events. Often, it is difficult to separate the reaction steps and study the kinetics of the individual steps. XRD does not suffer from these limitations and can therefore serve as an excellent complement to thermoanalytical techniques. Recent advances in instrumentation have enabled simultaneous and independent control of the temperature and the water vapor pressure in the sample chamber.

The dehydration kinetics of theophylline monohydrate ($C_7H_8N_4O_2 \cdot H_2O$) and ampicillin trihydrate ($C_{16}H_{19}N_3O_4S \cdot 3H_2O$) were studied by XRD (31). Dehydration of theophylline monohydrate resulted in a crystalline anhydrous phase, while the ampicillin trihydrate formed an amorphous anhydrate. In the case of theophylline, simultaneous quantification of both the monohydrate and the anhydrate was possible. By carrying out the reaction at several temperatures, the activation energy for the dehydration reaction was determined.

The enantiomers of pseudoephedrine were observed to react in the solid state to form the racemic compound (32). While the powder patterns of the enantiomers were identical, the racemic compound exhibited a different powder pattern. XRD permitted the simultaneous quantification of the disappearance of the enantiomers and the subsequent appearance of the racemic compound. The rate of disappearance of the enantiomers followed a diffusion-controlled reaction model. During the kinetic experiment, the sum of the weight fractions of the enantiomers and the racemic compound progressively decreased from an initial value of unity, suggesting the formation of an intermediate noncrystalline phase. This was confirmed by a steady increase in the background counts in the powder pattern.

The sweetener aspartame exists as a hemihydrate ($C_{14}H_{18}N_2O_5 \cdot 0.5H_2O$; ASH), under ambient conditions. When heated, ASH converted to aspartame anhydrate (ASA), which on further heating decomposed to form a diketopiperazine (DKP) derivative (33). The XRD patterns of ASH, ASA, and DKP showed pronounced differences (Fig. 12). XRD was used to simultaneously quantify the (i) disappearance of ASH and appearance of ASA in the first reaction and (ii) disappearance of ASA and appearance of DKP in the second reaction. For studying the kinetics of the first reaction, the peaks unique to ASH at 15.9 and $16.4^\circ 2\theta$ and the $17.1^\circ 2\theta$ peak of ASA were used. For the second reaction, the sum of the integrated intensities of the peaks at 10.2 , 11.0 , and $11.8^\circ 2\theta$ of ASA and the $13.0^\circ 2\theta$ peak of DKP were used. While the dehydration of ASH appeared to follow first-order kinetics, the cyclization of ASA was a nucleation-controlled process. Figs. 13 and 14 contain the dehydration and cyclization data at 118 and $180^\circ C$ respectively. Since the concentrations of the

Fig. 12 XRD patterns of aspartame hemihydrate (ASH), aspartame anhydrate (ASA) and diketopiperazine derivative (DKP). “*,” “o” and “+” denote the peaks unique to aspartame hemihydrate, aspartame anhydrate, and diketopiperazine derivative respectively. (From Ref. 33.)

crystalline reactant as well as the product were simultaneously monitored, mass balance calculations of the crystalline phases were possible at each time point. The reaction rate constants were obtained at several temperatures, which permitted the calculation of the activation energies of dehydration and cyclization from the Arrhenius plots.

Drug–Excipient Interactions

XRD is an excellent technique to study drug–excipient interactions, provided the drug and the excipients are crystalline. In a solid mixture, the powder pattern of each crystalline phase is produced independently of the other constituents. Thus the diffraction pattern of a powder mixture will be the summation of the diffraction patterns of the individual constituents. If the drug–excipient interaction results in a crystalline product, this will be characterized by the appearance of new peaks in the powder pattern. However, if the interaction results in an amorphous product, this will become evident from the broad halos in the pattern. Thus, irrespective of the nature of the product phase, XRD is capable of revealing such interactions.

Low Temperature XRD

The use of a cooling accessory permits XRD patterns to be obtained under subambient conditions. In pharmaceutical systems, the greatest utility of the technique is to monitor the crystallization of solutes in frozen solutions. Conventionally, differential scanning calorimetry has been the most popular technique for the characterization of frozen systems. However, as mentioned earlier, this

Fig. 13 Weight fractions of ASH and ASA as a function of time following storage of ASH at 118°C. The curves are drawn only to assist in visualizing the trends. (From Ref. 33.)

technique has some drawbacks: (i) It does not enable direct identification of crystalline solid phase(s). Moreover, it is difficult to draw any definitive conclusions about the degree of crystallinity. (ii) The interpretation of DSC curves is very difficult if there are overlapping thermal events. Low temperature XRD was found to be an excellent complement to differential thermal analysis in the characterization of water–glycine–sucrose ternary systems (34).

When sodium nafcillin solutions were frozen, the solute did not crystallize (35). However, annealing caused solute crystallization. It was also possible to monitor the amount of sodium nafcillin crystallizing as a function of annealing time. XRD was also useful to characterize the behavior of buffer solutions. While disodium hydrogen phosphate crystallized when an aqueous solution was frozen, the presence of monosodium hydrogen phosphate inhibited the crystallization of the former.

Fig. 14 Weight fractions of ASA and DKP as a function of time, following storage of ASA at 180°C. (From Ref. 33.)

In situ freeze-drying

The low temperature stage of the X-ray powder diffractometer was modified so that the sample chamber could be evacuated. As a result, the entire freeze-drying process was carried out *in situ* in the sample chamber of the XRD. The advantage of such a set-up is that the alterations in the solid state *during* the various stages of the freeze-drying process (cooling, primary, and secondary drying) were monitored (36). As mentioned earlier, annealing of frozen aqueous solutions of sodium nafcillin resulted in the crystallization of sodium nafcillin hydrate (the hydrate stoichiometry was not known). During the primary drying, there was partial dehydration resulting in the formation of partially crystalline sodium nafcillin hemihydrate (Fig. 15). It was possible to simultaneously monitor the disappearance of sodium nafcillin hydrate as well as the appearance of sodium nafcillin hemihydrate (Fig. 16). XRD revealed that this reaction was complete in about 40 min. The technique was also used to monitor the phase transitions during the freeze-drying of mannitol.

Implications in the Design of Freeze-Dried Formulations

Most solid-state characterization studies investigate the starting material and the freeze-dried end product. It will be useful and relevant to study alterations in the solid state *during* the different stages of the freeze-drying process, and this is enabled by low temperature XRD. The physical characterization of the phases at different stages of freeze-drying will not only aid in the optimization of the freeze-drying cycle, but will also facilitate the production of formulations that are physically and chemically stable.

ISSUES AND CHALLENGES IN XRD

Most materials of pharmaceutical interest are organic compounds. Jenkins has comprehensively discussed the problems associated with the X-ray diffractometric analysis of organic materials (37): 1) The unit cells of organic compounds are often large, resulting in low angle lines (large d-spacings). The accuracy of d-spacing data tends to decrease as the d-spacing increases, particularly when the d-spacing value is higher than 8 Å. 2) The unit cells are often of low symmetry resulting in complex powder patterns. 3) Since organic compounds usually have low mass attenuation coefficients, the X-rays can penetrate

Fig. 15 The XRD patterns of (a) “as is” sodium nafcillin, (b) frozen solution of sodium nafcillin (40 wt%) annealed at -4°C for 1 h, and (c) after freeze-drying the annealed system. The “as is” sodium nafcillin was a monohydrate. Annealing is believed to result in the crystallization of a higher hydrate of sodium nafcillin (unknown stoichiometry). The freeze-dried material was partially crystalline sodium nafcillin hemihydrate. (From Ref. 35.)

deep into the specimen leading to large beam transparency errors. 4) Finally, organic compounds are especially prone to preferred orientation (preferred orientation is discussed in the next section).

Sample Preparation

There are many different methods of sample preparation. Most of the sample holders contain a cavity into which the

Fig. 16 Real time monitoring of the phase changes during the freeze-drying of sodium nafcillin by in situ XRD. The disappearance of sodium nafcillin hydrate (“Hydrate”) and the appearance of sodium nafcillin hemihydrate (“Hemihydrate”) were simultaneously quantified. The curves were drawn to assist in visualizing the trends. (From Ref. 36.)

powder sample is filled, usually from the top. However, the side-loading (also referred to as side-drift) method is considered the best packing method (1, 38). Unfortunately, many commercial sample holders do not permit sample filling by this method. As a result, holders have been specially fabricated for this purpose (23). Since organic compounds predominantly consist of atoms with low atomic numbers, there will be significant penetration of X-rays. This can result in peak displacement as well as broadening. Detailed information on sample preparation is available in the literature (4).

When only a very small amount of powder sample is available, the use of a low-background (also referred to as zero background) support is advisable. The support is a quartz or silicon plate cut along a nondiffracting crystallographic direction, which is then polished (1). This results in a very low background and improves the signal-to-noise ratio and enables XRD patterns to be obtained with extremely small amounts of sample.

Sources of Error

There are numerous sources of error in XRD. Two of these are discussed hereafter.

Preferred orientation

Reliable and reproducible results can only be obtained if the sample is prepared carefully. When a sample is packed in an X-ray holder, the distribution of crystal orientations can be nonrandom, and this condition is referred to as preferred orientation. Jenkins and Snyder (1) have elegantly illustrated this point in Fig. 17. Atoms bond together, in a unique manner, to form unit cells. If the unit cells are grouped so as to have long-range order, a crystalline material is obtained. In the absence of long-range order, the material is amorphous (noncrystalline). A powder sample is composed of crystallites. When the crystallites in a sample are oriented in some particular (nonrandom) manner, they are said to exhibit preferred orientation (1). Ideally, random orientation of individual crystallites is desired. It is recognized that preferred orientation is a commonly encountered condition in powdered samples (2).

Grinding the sample and thereby reducing the particle size can decrease preferred orientation. However, grinding can cause lattice disorder (decrease in crystallinity) and also induce other undesirable transitions, such as polymorphic transformations. Moreover, when the particle size is very small, particle size induced peak broadening can be observed. This effect, observed when the particle size is $<10,000 \text{ \AA}$ ($1 \mu\text{m}$), is simply a consequence of the

Fig. 17 The structural makeup of solids. (From Ref. 1.)

limited number of planes that are diffracting X-rays (Fig. 18). The particle (crystallite) size is related to the X-ray line width according to the Scherrer equation (1). It is important to recognize the fact that line broadening can be brought about by a loss in crystallinity as well as a decrease in particle size. In the pharmaceutical literature, there is a tendency to automatically attribute line broadening to loss in crystallinity. Such a conclusion, while usually correct, can be occasionally erroneous.

Fig. 18 The width of X-ray lines as a function of particle dimension. (From Ref. 1.)

Measurement of line intensity

When measuring intensity, the integrated line intensity (peak area) and not the maximum intensity (peak height) must be measured. Variations in lattice strain and particle size can significantly influence the line shape, but their effect on the integrated intensity will generally be minimal (2).

Other sources of error

There are numerous other sources of error that are particularly relevant while conducting quantitative XRD studies. These are discussed in detail in the literature (Refs. 1–3, 6).

ACKNOWLEDGMENT

We thank Mr. Rahul Surana for his assistance in the preparation of the manuscript.

INTRODUCTION

Dispersion systems represent an important class of pharmaceutical dosage forms such as emulsions, suspensions, microspheres, liposomes, and nanoparticles. The medium of these systems is mainly aqueous in nature and the dispersed phase can be either solid particles or immiscible liquid droplets. Electrical charges are developed by several mechanisms at the interface between the dispersed phase and the aqueous medium (1). The two most common mechanisms are the ionization of surface functional groups and the specific adsorption of ions. These electrical charges play an important role in determining the interaction between particles of the dispersed phase and the resultant physical stability of the systems, particularly for those in the colloidal size range. For dispersed systems which are used as drug carriers, i.e., liposomes and microparticles, their *in vivo* fate and therapeutic efficacy are both affected by these surface charges. Therefore, the understanding of this electrical phenomenon becomes essential in developing these systems.

The presence of these surface charges influences an uneven distribution of charges (ions) surrounding the particle and the development of an electrical potential (or an electrical field) between the surface and the electrically neutral bulk-solution phase of the system. The surface charge and the counterions in its vicinity give rise to an electric double layer as shown in Fig. 1. The double layer is divided into two parts separated by a plane called the Stern layer which is located at about a hydrated-ion radius from the surface. Usually, the number of ions in the Stern layer is smaller than that needed to achieve neutralization of the surface charge and the balance of the neutralization occurs in a Gouy–Chapman layer outside the Stern layer. The surface potential (ψ_0) and the Stern potential (ψ_d) are not readily measured experimentally; instead, the potential between a stationary fluid layer enveloping the particle and the bulk-solution phase can be determined by measuring the mobility of the particle in an applied electrical field.

The potential between the tightly bound surface liquid layer (shear plane) of the particle and the bulk phase of the solution is called zeta potential (ζ). It can provide a measure of the net surface charge on the particle and potential distribution at the interface. Zeta potential serves as an important parameter in characterizing the electrostatic interaction between particles in dispersed systems and the properties of the dispersion as affected by this electrical phenomenon.

METHOD AND INSTRUMENTATION

Microelectrophoresis

The most common method for determining the zeta-potential is the microelectrophoretic procedure in which the movements of individual particles under the influence of a known electric field are followed microscopically. The zeta potential can be calculated from the electrophoretic velocity of the particles using the Helmholtz–Smoluchowski equation,

$$U_{mp} = V_{mp}E = \zeta \epsilon \eta \quad (1)$$

where U_p is the electrophoretic mobility, V_p is the electrophoretic velocity, E is the electric-field strength, ζ is the zeta potential, ϵ is the permittivity, and η is the viscosity of the medium.

It is important to realize that the observed electrophoretic migration is the sum of two contributions, one of which is the electro-osmotic flow of the medium through the cell. The glass of the sample cell generally bears negative charges, so that a diffuse layer of cations exists adjacent to them. This sets up an electro-osmotic flow through the cell (with or without particles). This flow has its maximum value at the center, since the layer of fluid adjacent to the walls is stationary. The particles tracked at the center of the cell therefore possess the maximum increment in velocity because of the electro-osmotic flow. Since there is no net liquid flow through the closed cell,

Fig. 1 A schematic representation of the electric double layer around a particle with negative surface charges and electrical potentials surrounding the particle.

a back-pressure builds up which causes fluid flow in the reverse direction in the core of the cell. In the steady state, these flows balance, giving rise to a velocity profile as shown in Fig. 2. Therefore, the tracking of particles at a location where the medium experiences no net flow becomes important in yielding an accurate electrophoretic mobility measurement. A velocity profile has been derived for the liquid contained in a cylindrical electrophoretic cell. The location with zero liquid flow is shown to be 14.6% of the cell diameter inside the surface of the capillary. The location of the surface of zero liquid flow in cells of rectangular cross section has also been determined. For a cell in which the direction of migration is relatively long compared to the width of the cell, the surface with zero liquid flow lies 21.1% of the cell depth above the bottom and below the top of the working compartment. Experimentally, particles tracked at these positions of the sample cell will display their mobility uncomplicated by the electro-osmotic effect.

The rate of particle migration can be determined by measuring with a stopwatch the time required for a particle

Fig. 2 The velocity profile of fluid flow in an electrophoretic cell.

Fig. 3 A diagram of light paths in the rotating prism method of microelectrophoretic measurement.

to travel between the marks of a calibrated graticule in the microscope eyepiece. Since many particles are usually measured in order to get good statistical results, the measurement of a sample may take 30 min or even longer. As the time of measurement increases, however, the susceptibility to errors also increases. For example, a long measurement time will cause convection currents generated by heating of the sample, air-bubble formation, settling of particles, and electrode reactions. These potential errors can be avoided if the measurement is taken much more quickly without loss of accuracy. A rotating prism method employed by the Lazer Zee Meter (Model 50,1 Pen Kem, Inc.), allows the operator to measure more than 10 particles simultaneously. Data are thereby attained more rapidly and, consequently, with fewer time-dependent errors. Fig. 3 shows a diagram of light paths in the rotating prism method (2). The microscope is focused on the stationary layer of the cell (with no fluid flow). Special cylindrical optics compress the laser beam into an illumination sheet of laser light. A vertical adjustment is provided to vary the height so that it coincides with the focal plane of the microscope. A cube prism inside the microscope causes the viewed image to translate at a rate proportional to the prism's speed of rotation. The applied electric field causes the particle to move at an electrophoretic velocity proportional to the mobility and the applied voltage. Adjustment of the potentiometer causes the prism to rotate at a rate proportional to potentiometer voltage times applied voltage. When the image velocity caused by prism rotation is equal and opposite to the mean electrophoretic velocity, the cloud of particles appears stationary. The applied voltage is therefore proportional to the mean particle electrophoretic mobility. The mobility value is scaled by an appropriate constant in the digital meter and the computed zeta potential is displayed on the 3-digit readout.

In spite of a major improvement gained from the rotating prism method, there are still serious limitations in the use of microelectrophoresis in determining zeta potential. First, this technique cannot be applied to dense dispersions, i.e., the number density of the particles must

be very low. This can sometimes, but not always, be remedied by filtering the sample and diluting a small amount of the original dispersion with a large volume of filtrate. Second, it cannot be applied to particles less than about 0.2 μm in diameter because they are not easily visible in the ultramicroscope, though the particle-size range may be extended by adsorbing the colloidal particles (i.e., protein molecules) on suitable carrier particles. An additional and unresolvable problem with very small particles is the blurring effect imparted by Brownian motion. Furthermore, the microelectrophoretic technique cannot be used to determine mobility distributions or to separate multimodal mobility distributions.

Electrophoretic Light-Scattering (3–5)

Electrophoretic light-scattering is a technique which determines the electrophoretic velocities by measuring the Doppler shifts of scattered laser light. The electrophoretic mobility can be expressed by

$$U_p = \Delta\nu\lambda_0/2nE\sin(\theta/2) \quad (2)$$

where U_p is electrophoretic mobility, $\Delta\nu$ is the Doppler frequency shift, λ_0 is the wavelength of the laser in a vacuum, n is the index of refraction of the medium, E is the electric field applied, and θ is the scattering angle. Since a He–Ne laser light has a frequency of about 6.0×10^{14} , a direct measurement of frequency shifts ranging from zero to several hundred Hz may be problematic because of the difficulty in measuring a small difference between large quantities. However, this can be overcome by using the principle of heterodyning, which measures the difference in frequency resulting from a reference beam and the Doppler-shifted beam.

When the Brownian motion of the particles is negligible, the power spectrum which is generated by the autocorrelation function of the scattered light has a very narrow peak. However, the actual spectral peak has considerable line width attributable to the Brownian motion of the particles and a distribution of electrophoretic mobilities. The separation of these two sources of spectral-peak broadening is critical because, without such a separation, a measurement of electrophoretic mobility at a single angle provides information only about the peak position (Doppler shift). The shape of the peak (Doppler broadening), being attributable to either of the two effects, cannot be interpreted with a single-angle measurement. Simultaneous multiple-angle measurements allow peak shapes to be analyzed to give accurate measurement of the electrophoretic mobility and the subsequent determination

of zeta potential according to the Helmholtz–Smoluchowski equation (Eq. 1).

The DELSA 440 (Coulter Scientific Instruments) is a laser-scattering particle electrophoretic analyzer that measures the electrophoretic mobility distribution and zeta-potential distribution (6). This instrument provides simultaneous measurements of line widths at four different angles so that the motion of the particle can be decomposed with high resolution into components caused by electrophoretic and diffusional motions. Therefore, particle sizing can also be carried out by the same instrument simultaneously with electrophoretic mobility determinations. Fig. 4 presents a schematic diagram of the DELSA 440 system. Other commercially available electrophoretic analyzers using the laser light-scattering principles are the Zetasizer 3 (Malvern Instruments), ZetaPlus (Brookhaven Instruments), System 3000 (PenKem, Inc.), and NICOMP 380/ZLS (Particle Sizing Systems).

Electrokinetic Sonic Analysis (3, 6, 7)

When a colloidal dispersion is subject to ultrasonic waves, a density difference between the dispersed phase and the continuous phase will cause relative motion between the particles and the surrounding fluid. This relative motion means that there will be a periodic interchange of the charged particle surface and the oppositely charged counter-ions in the electric double layer. This interchange results in the development of an alternating dipole at the frequency of the applied ultrasound wave. This effect is termed the ultrasound vibration potential (UVP). The UVP effect in colloids is also referred to as the colloid vibration potential or CVP. An effect opposite that of CVP is generated, when an alternating electric field is applied to a colloidal dispersion, creating an acoustic wave which, by means of a piezoelectric device, may be transduced into an alternating potential of a certain amplitude, depending on the dispersion and the electric double-layer properties. This is called the electrokinetic sonic amplitude (ESA). These two phenomena are both known as electro-acoustic effects.

Fig. 4 A schematic diagram of the DELSA 440 system.

The magnitude of these effects is directly proportional to the electrophoretic mobility of the particles. The mobility determined by either electro-acoustic effect is the dynamic or AC mobility of the particle.

The dynamic mobility which is determined by the electro-acoustic effects differs from the low-frequency or DC mobility that is determined by electrophoresis because of the effects of particle inertia which cause particle velocities in an alternate field to become out of phase with the applied field. The higher the frequency, the greater is the phase lag between the particle and the applied field. Dynamic mobility (U_d) is a function of frequency, particle size, particle density, and particle zeta potential. These inertial effects arise in both ESA and CVP measurements. In the case of spherical particles with thin double layers and low zeta potential, the equation below can be applied:

$$U_d = (\epsilon\zeta/\eta)G(\alpha) \quad (3)$$

where $G(\alpha)$ is the inertial term. The formula for dynamic mobility is identical to the well-known Helmholtz–Smoluchowski equation (Eq. 1) for DC electrophoretic mobility except for the $G(\alpha)$ term.

A linear relationship exists between the ESA or CVP amplitude and the volume fraction of the suspended particles. At relatively high-volume fractions, hydrodynamic and electric double-layer interactions lead to a non-linear dependence of these two effects on volume fraction. Generally, non linear behavior can be expected when the electric double-layer thickness is comparable to the interparticle spacing. In most aqueous systems, where the electric double layer is thin relative to the particle radius, the electro-acoustic signal will remain linear with respect to volume fraction up to 10% by volume. At volume-fractions that are even higher, particle-particle interactions lead to a reduction in the dynamic mobility.

The commercial systems for zeta-potential determination using these electro-acoustic effects are typified by the AcoustoSizer 8000 (Matek Applied Sciences) consisting of five main components (Fig. 5). The synthesizer

produces a continuous sinusoidal voltage which feeds into the gated amplifier. This creates a sinusoidal voltage pulse across the cell which contains the dispersion. The resulting ESA sound waves are converted by a pressure transducer in the cell to an electrical signal, which then passes to the signal processing electronics. The electronics extract the amplitude and the phase of the ESA signal, storing them in the computer housed in the AcoustoSizer.

A schematic diagram of the cell is shown in Fig. 6. The dispersion is located in the region between the pair of electrodes. The pulse from the gated amplifier is applied across these electrodes, generating the ESA sound waves. Voltage pulses rather than continuous sinusoids are applied to avoid interference by the sound wave emanating from the electrodes. The use of pulsed signals also avoids electrical heating of the suspension and the complications of multiple reflections of the waves at the electrodes and at the ends of the rods. The voltage pulse produced by the sound wave in the transducer on the right passes into the signal-processing electronics, which measures the amplitude and phase of the sinusoidal component of the pulse. These data are passed to the computer where it is stored for subsequent processing.

Since the ESA signal depends on particle motion and also on the acoustic property of the dispersion, the determination of particle motion from the ESA signal requires knowledge of the acoustic impedance of the dispersion. This parameter is measured using sensors associated with the rod on the left immediately after each ESA measurement. The signals from these two rods are stored in the computer and are subsequently converted to a particle-velocity spectrum, and from that the zeta potential and size information is determined. The AcoustoPhor 8000 (PenKem, Inc.) is another example of a commercial system which determines zeta potential and the particle size of dispersions using these electro-acoustic effects.

APPLICATIONS

The practical significance of zeta-potential measurement lies in the fact that strong empirical correlation exists between the measured zeta potential of the system and the properties of the system which are the manifestation of the electrostatic interfacial phenomenon. Since the measurement of zeta potential can be conveniently performed, it becomes an ideal parameter for use in routine testing. Zeta-potential control has been successfully applied to various technical fields involving colloidal and non-colloidal systems.

Fig. 5 An AcoustoSizer signal processing block diagram.

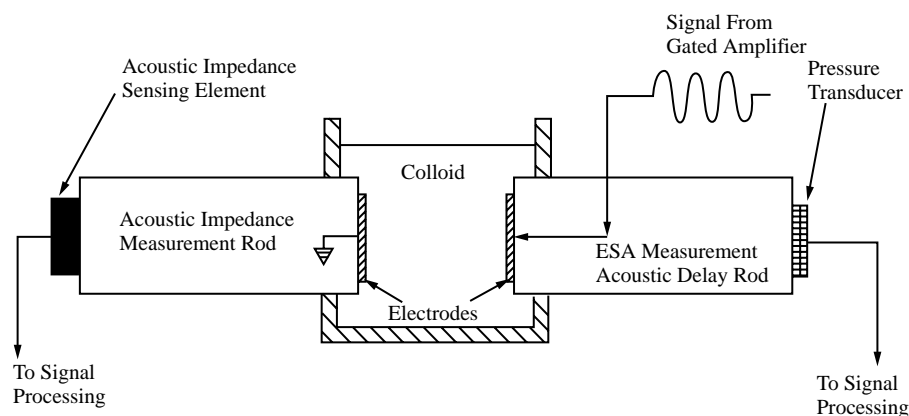

Fig. 6 A schematic diagram of AcoustoSizer measurement cell.

Colloid Stability (3, 8, 9)

The physical stability of a colloidal system is determined by the balance between the repulsive and attractive forces which is described quantitatively by the Deryaguin–Landau–Verwey–Overbeek (DLVO) theory. The electrostatic repulsive force is dependent on the degree of double-layer overlap and the attractive force is provided by the van der Waals interaction; the magnitude of both are a function of the separation between the particles. It has long been realized that the zeta potential is a good indicator of the magnitude of the repulsive interaction between colloidal particles. Measurement of zeta potential has therefore been commonly used to assess the stability of colloidal systems.

Electrostatic repulsive energy, V_R , at a given inter-particle distance is the work which must be performed to bring the particles to a specific point. Using the Debye–Huckel low-potential approximation and assuming equal spheres, V_R can be described by

$$V_R = 2\pi\epsilon a\psi_d^2 \ln(1 + \exp[-\kappa H]) \quad (4)$$

where a is the particle radius, H is the distance of separation between the two particles, and κ is the Debye parameter. The magnitude of V_R decreases in an approximately exponential fashion with increasing H and that its range decreases by increasing κ (i.e., by increasing electrolyte concentration and/or counter-ion charge number). V_R can be also influenced by other specific factors. Counter-ion adsorption in the Stern layer may cause a reversal of charge, so that V_R will be zero at the reversal-of-charge concentration and will be positive (repulsion) at both below and above this concentration.

The attractive-force component between particles in a colloidal system is developed by summation of the London

dispersion forces between all atom pairs in the particles. Neglecting retardation effects, the expression for the attractive energy V_A between two particles of radius a at a distance of separation H_0 , for $a \gg H_0$, is

$$V_{rma} = A, a12H_0 \quad (5)$$

where A is the effective Hamaker constant describing the attraction between the particles and the dispersion medium. It is apparent that V_A decreases as an inverse power of the distance between the particles.

According to DLVO theory, the total energy of interaction between colloidal particles is given by the sum of the attraction (V_A) and repulsion (V_R) energies:

$$V_T = V_R + V_A \quad (6)$$

Fig. 7a shows the total interaction energy curve for a colloidal system. At very close distances between the particles, the Born repulsion between adjoining electron clouds predominates, and the net interaction is repulsion. However, at slightly greater distances, the van der Waals attraction predominates over the electrostatic repulsion, and the net interaction is strong attraction as shown by the deep potential energy minimum V_p . At even greater distances, the net interaction is moderate attraction (a shallow secondary minimum V_s) because with increasing distance between two particles, electrostatic repulsion weakens more rapidly than the van der Waals attraction energy. At intermediate distances, the electrostatic repulsion predominates and the net interaction becomes repulsion, with an energy barrier, V_m .

The attraction energy arising from van der Waals forces does not vary significantly with changes in the surface potential and electric double-layer properties of the colloidal particles. By contrast, changes in these two parameters have significant impact on the repulsion energy

Fig. 7 Variation of the attraction and repulsion energies and the total energy of interaction between two colloidal particles with interparticle distance.

component of the total interaction energy. Therefore, at greater distances, a further increase in electrostatic repulsion will result in a total repulsive net interaction curve without the secondary minimum (Fig. 7b). However, as the repulsive component of the interaction energy diminishes (i.e., the electrolyte concentration increases), the interaction curve becomes totally attractive and rapid coagulation (controlled by particle-diffusion rate) of the colloidal particles takes place (Fig. 7c).

An empirical relationship was developed between the zeta potential and the coagulation behavior of a variety of systems. Deryaguin shows that a rapid decrease in stability can be expected when the following conditions are met (3).

$$4\pi\epsilon\xi^2/\kappa[A] \quad (7)$$

For a given system, A and ϵ are fixed; therefore, varying the electrolyte (in type and concentration) should produce instability at a particular value of ξ^2/κ . The validity of using zeta potential in describing the coagulation process should come as no surprise because it characterizes the potential of the diffuse part of the electric double layer which is involved in double-layer overlap and which plays an important role in the coagulation process. When the zeta potential is sufficiently high to produce a potential

barrier opposing coagulation, the rate of coagulation is slowed by a factor W , called the stability ratio, defined as the ratio of the total number of particle collisions to the number of collisions forming permanent doublets. Wiese and Healy reported an excellent correlation between the theoretical values for W (calculated from the zeta potential) and the experimental values for TiO_2 and Al_2O_3 sols as a function of pH (Fig. 8) and electrolyte (KNO_3) concentration (10). Rapid coagulation, whether induced by pH or KNO_3 concentration changes, occurs at a value of $|\zeta| \leq 14 \pm 4$ mV, corresponding to $\xi^2/\kappa = 6 \times 10^{-4} (\text{mV})^2 \text{ cm}$.

Pharmaceutical Systems

Most of the pharmaceutical dispersions can be classified as colloidal systems, although this depends upon the size of their dispersed phase. Therefore, in general, the theoretical and empirical relationships between zeta potential and colloid stability are applicable to the physical stability of these pharmaceutical systems. However, the practical aspects of applying zeta potential to these systems may vary because of differences in the chemical composition and physical state of their dispersed and continuous phases. In addition, the practical significance of zeta-potential

Fig. 8 Comparison of theoretical and experimental stability ratios for TiO_2 (0.05 g/L) and Al_2O_3 (0.15 g/L) colloids in 10^{-4}M KNO_3 .

measurement may be different for products which differ in their clinical requirements such as route of administration and consequent in vivo disposition.

Emulsions

Emulsions have been widely used as vehicles for oral, topical, and parenteral delivery of medications. Although the product attributes of an emulsion dosage form are dependent on the route of administration, a common concern is the physical stability of the system, in particular the coalescence of its dispersed phase and the consequent alteration in its particle-size distribution and phase separation. The stabilization mechanism(s) for an emulsion is mainly dependent on the chemical composition of the surfactant used. Electrostatic stabilization as described by DLVO theory plays an important role in emulsions (O/W) containing ionic surfactants (11). For O/W emulsions with low electrolyte content in the aqueous phase, a zeta potential of 30 mV is found to be sufficient to establish an energy maximum (energy barrier) to ensure emulsion stability (11). For emulsions containing nonionic surfactants (polymers), the principal stabilization mechanism is the repulsion between the adsorbed polymer chains on

the surface of the oil globules called steric stabilization (11). In such a case, zeta-potential measurement may have limited values with respect to emulsion stability.

In the past, injectable emulsions were administered intravenously to provide patients with vegetable oils as a major energy source in nutrition therapy (12). In recent years, injectable emulsions have been found to be very effective vehicles for the parenteral delivery of water-insoluble drugs (13). Because of toxicological considerations, surfactants which are used in the formulation of injectable emulsions have been largely limited to mixtures of phospholipids which are either derived from egg (egg yolk lecithin) or soybean (soybean lecithin). The majority of the phospholipids (80–90%) are phosphatidylcholine (PC) and phosphatidylethanolamine (PE), which are uncharged at physiological pH. But the presence of small quantities (2–5%) of acidic components, largely phosphatidylserin (PS) and phosphatidylglycerol (PG), which are ionized at pH 7, confers a surface charge of approximately -40 to -50 mV on the emulsion particles (14). Therefore, the stability of these emulsions is mainly attributable to electrostatic stabilization. Any factors which alter the surface potential are likely to have an impact on overall emulsion stability. The physical instability of an injectable emulsion as manifested by an increase in particle size ($>5\text{ }\mu\text{m}$) will result in serious clinical consequences such as formation of pulmonary emboli (15). Therefore, the extent of electrostatic stabilization of an injectable emulsion as measured by its zeta potential has been an important parameter in the characterizing and monitoring of its physical stability.

A relative wealth of information relating to the application of zeta potential to injectable emulsions has been documented with respect to the use of total nutrient admixtures (TNA) (16). Total nutrient admixtures are prepared by mixing the lipid emulsion with other components (i.e., dextrose, amino acids, and electrolytes) in a single container prior to administration. Depending on composition, the mixtures vary widely in their stability and may show clinically unacceptable coalescence after different periods of storage time.

When the electrostatic stabilization of the emulsion is considered, the electrolytes (monovalent and divalent) added to the mixture are the major destabilizing species. The zeta potential of the emulsion particles is a function of the concentration and type of electrolytes present. Two types of emulsion particle-electrolyte (ions) interaction are proposed: nonspecific and specific adsorption (16). In nonspecific adsorption the ions are bound to the emulsion particle only by electrical double-layer interactions with the charged surface. As the electrolyte concentration is increased, the zeta potential asymptotes to zero. As

Fig. 9 Zeta potential and flocculation rate of a parenteral emulsion in the presence of a nonspecifically adsorbing electrolyte (a) and a specifically adsorbing electrolyte (b).

the electrostatic repulsion decreases, a point can be found where the attractive van der Waals force is equal to the repulsive electrostatic force and flocculation of the emulsion occurs (Fig. 9a). This point is called the critical flocculation concentration (CFC).

DLVO theory predicts that the CFC should vary inversely with the sixth power of the ion charge. The application of CFC alone fails to correlate the TNA stability with electrolytes in the mixtures. This is because divalent ions (calcium and magnesium) adsorbed specifically on the emulsion particles through their complexation with the negatively charged acidic phospholipids. Fig. 9b demonstrates the relationship between the concentration of a specifically adsorbed ion and the zeta potential and flocculation rate of an injectable emulsion. The increase in electrolyte concentration causes the particle charge to pass through zero; this is referred to as the point of zero charge (PZC). At this point the flocculation rate is at maximum; a further increase in electrolyte concentration causes a surface-charge reversal of the particles and increases in zeta potential (opposite sign) as well as a decrease of the flocculation rate from its maximum value.

The effect of pH on the stability of an injectable emulsion was also followed by measuring its zeta potential (Fig. 10). At pH 7 the ionization of PS and PG imparts a surface negative charge (-30 to -50 mV) to the emulsion

particles. As the pH is reduced, this ionization is suppressed until the charge is zero at a pH of 3.2. Further decreases in pH cause the protonation of the phospholipid and a positive surface charge (positive zeta potential). Significant progress has been made in relating the electrokinetic properties of phospholipid-stabilized emulsions to their instability when influenced by other TNA ingredients (17, 18). Washington and his coworkers have attempted to develop a model to predict emulsion stability in TNAs using DLVO-based methods in the measurement of the zeta potential of the system (19).

Suspensions

Pharmaceutical suspensions are dispersions of solid particles in a suspending medium or vehicle (usually aqueous in nature). When the suspended solids are less than $1\text{ }\mu\text{m}$, the system is referred to as a colloidal suspension. When the particle sizes are greater than about $1\text{ }\mu\text{m}$, the system is called a coarse suspension. The practical upper limit for particles in a coarse suspension is approximately $50\text{--}75\text{ }\mu\text{m}$. Depending on the affinity or interaction between the dispersed phase and the dispersion medium, a colloidal dispersion can be classified as lyophilic (hydrophilic) or lyophobic (hydrophobic) (20).

The dispersion of hydrophilic particulate solids in water occurs spontaneously and gives rise to a thermodynamically

Fig. 10 Zeta potential of a parenteral emulsion as a function of pH.

stable system such as colloidal silicone dioxide or microcrystalline cellulose. Hydrophobic solids are not easily wetted and are not dispersed spontaneously in water as sulfur, clays, and most nonpolar organic compounds. The van der Waals attractive forces between particles cause them to aggregate, since the solvation forces which promote dispersal in water are weak. Therefore, aqueous dispersions of hydrophobic solids can only be stabilized kinetically to resist flocculation and coagulation, which can be defined by referring to the total interaction energy curve (Fig. 7). Flocculation indicates the association of particles in the secondary minimum and coagulation is the aggregation of particles in the primary minimum. Since the attractive forces between particles in a flocculated system are relatively weak, they can be redispersed and the process is reversible. In contrast, coagulation is irreversible as attractive forces operating between particles in the primary minimum are difficult to overcome.

When electrostatic repulsion is predominant between particles in a suspension, it is called a deflocculated system. For particles with a diameter of 2–5 μm , Brownian movement counteracts sedimentation to a measurable extent at room temperature by keeping the dispersed particles in random motion. This results in a system which is physically stable with respect to sedimentation and flocculation (20). However, in a deflocculated suspension consisting of larger particles (coarse), gravitational force counteracts Brownian movement and sedimentation occurs (21). At the bottom of the container, a compact sediment with strong attractive forces between the particles is formed and it cannot be easily

Fig. 11 A caking diagram showing the flocculation of a bismuth subnitrate suspension by means of the flocculating agent, potassium monobasic phosphate.

redispersed. This phenomenon is referred to as caking. The prevention of caking has been one of the main objectives in preparing stable coarse suspensions (21, 22). Although flocculation is referred to as a physical instability of colloids, flocculated suspensions are pharmaceutically acceptable since they are noncaking. In a flocculated suspension, particles attract each other (at the secondary minimum) loosely to form flocs which tend to settle together, creating a distinct boundary between the sediment and the supernatant. Particles in flocs are thereby easily redispersed after settling.

Controlled flocculation is a process by which flocculation of particles in a suspension is purposely produced by adding flocculating agents. One of the most effective methods of achieving controlled flocculation is to reduce the electrostatic repulsive forces between particles (21, 22). Electrolytes have been shown to be effective flocculating agents. Zeta-potential measurement has been a valuable tool in monitoring and evaluating the influence of various electrolytes on the flocculation phenomena in coarse suspensions (23). Sedimentation volume F , which is the ratio of the volume of sediment to the original volume of the suspension, is a useful parameter in measuring the extent of flocculation of the suspension. An excellent correlation between the zeta potential, sedimentation volume, and caking was found for a series of bismuth subnitrate suspensions containing various concentrations of potassium phosphate monobasic (Fig. 11) (24). The addition of potassium phosphate monobasic causes a decrease in the zeta potential of the suspension because of partial neutralization of the positive

surface charge on the bismuth subnitrate particles. With the decrease in the zeta potential (positive), the suspension becomes flocculated and noncaking, accompanied by an increase in the sedimentation volume. The continued addition of electrolyte causes the zeta potential to fall to zero and then increases in a negative direction. The suspension remains flocculated until the zeta potential becomes sufficiently negative to effect deflocculation of the system, which is shown by a decrease in the sedimentation volume and an increase in caking tendency.

Zeta potential has also found an application in relating the surface-charge characteristics of a suspension to properties other than physical stability. Heyd and Dhabhar improved the fluidity of concentrated antacid suspensions by adding a colloidal polyelectrolyte (carrageenan sodium) which is called a fluidizing agent (25). As the concentration of the fluidizing agent increases, the zeta potential of the suspension changes from positive to negative, accompanied by a reduction in viscosity of the suspension. The mechanism for this viscosity-thinning phenomenon is believed to be the selective adsorption of the negatively charged fluidizing agent onto the positively charged antacid particles. This imparts an electronegative charge (as measured by the zeta potential) onto the antacid particles, decreasing the demand for water.

In the literature, the reported use of zeta potential measurement for nonaqueous suspensions is relatively infrequent because nonaqueous suspensions only represent a small percentage of all medicated suspensions. Su and others evaluated the flocculation–deflocculation behavior of cefazolin sodium in nonaqueous media and the effect of surfactants as measured by zeta potential along with sedimentation and porosity measurements (26). A significant difference in zeta potential was observed when the particles were dispersed in peanut oil and ethyl oleate. The addition of lecithin reduced the zeta potential of cefazolin sodium, resulting in a deflocculated state accompanied by a decrease in sedimentation volume. The effect of surfactant excipient on the zeta potential of salbutamol in trichlorofluoroethane (P113) for metered-dose inhalation was determined (27). Although the zeta potential of the particles is decreased (more negative) by the addition of oleic acid, the overall zeta potential is too low to be effective in providing the system with adequate electrostatic stabilization, particularly in media with a low dielectric constant (organic solvents).

Microparticulate drug-delivery systems, including microspheres and nanoparticles, are suspensions when they are administered in a liquid medium. Microspheres are solid particles containing dispersed drug in either solution or microcrystalline form and range in size from

1 to 1000 μm . Although most microspheres are outside the conventional colloidal size range, in pharmaceutical literature microspheres with sizes up to approximately 15 μm are still considered as colloidal delivery systems (28). Nanoparticles are similar to microspheres but have particle sizes in the range of 0.01–1 μm ; therefore, they form colloidal suspensions when dispersed in a liquid medium (29). Zeta-potential measurement is an important surface-characterization technique which provides information regarding the surface charge of these microparticulate systems. The effect of surface charge (zeta potential) on the physical stability of these systems (i.e., aggregation) can be predicted using the DLVO theory, although steric stabilization plays an important role in systems with surface-adsorbed macromolecules.

When the microparticles are administered intravenously, surface charge is an important parameter affecting the interaction between the microparticles and other biological components of the body and their subsequent *in vivo* distribution and disposition (30). Tabata and Ikada reported that phagocytosis of polymer microspheres by macrophages is enhanced as the absolute value of zeta potential increases for both the negatively charged and the positively charged surfaces, while the lowest phagocytosis is shown for the surface with a zeta potential of zero (31). The uptake of charged serum components by nanoparticles (opsonization) in blood is considered to be the first step leading to phagocytosis by liver and spleen macrophages. Muller and his coworkers determined the increase in zeta potential of nonparticles in serum as a measure of the extent of opsonization and used this as selection criteria for *i.v.* drug carriers avoiding liver/spleen uptake (32).

Liposomes

Liposomes are phospholipid-based vesicles which have been studied as delivery systems to target drugs to specific sites in the body (33–35). The surface of a liposome can be neutral or negatively or positively charged, depending on the composition of lipids used. For charged liposomes, their surface potential is a critical factor affecting their physical stability and *in vivo* performance. Instead of their surface potential, zeta-potential measurement is frequently used in the investigation of the behavior of liposomes as influenced by their surface charge. Liposomes in aqueous dispersions have a tendency to aggregate and subsequently fuse on storage. This physical instability potentially limits their application as dosage forms.

Crommelin incorporated charge-inducing components in liposome bilayers to produce electrostatic repulsion between liposomes, thus increasing the shelf life of the dispersion (36). He investigated the effect of including

stearylamine or phosphatidylserin on the zeta potential of phosphatidylcholine-cholesterol-containing liposomes. A correlation between the aggregation stability of negatively charged liposomes and the increments in the surface-charge density at both low and high ionic strength was established, whereas the positive liposome dispersions were found to be unstable.

Carrión and his coworkers investigated the effect of incorporating phosphatidic acid on the zeta potential and aggregation of large unilamellar vesicle liposomes of phosphatidylcholine in the presence of neutral electrolytes (37). Their results show that increasing concentrations of phosphatidic acid in lipid bilayers resulted in high zeta potential and enhanced physical stability of the liposomes. The destabilizing effect of divalent cations (i.e., calcium ions) on charged liposomes has been well documented and is attributable to the reduced surface potential of the liposomes as the result of cation binding (38–40).

The effect of calcium ions on the aggregation behaviors of neutral liposomes composed of egg phosphatidylcholine and dipalmitoylphosphatidylcholine was investigated by Mosharraf and coworkers (41). Both systems displayed a high negative zeta potential in deionized water, probably the result of adsorption of hydroxyl ions. A reasonable correlation was found in both cases between particle-size increase and zeta potential decrease of the system, suggesting that the mechanism by which the aggregation takes place is related to the surface-charge characteristics. Although it has long been established that liposomes composed of neutral phospholipids acquire negative surface charge via anion adsorption, Makino and his group in Japan found that neutral liposomes exhibit negative zeta potential in buffer solution containing no chloride ion (42). They also reported that changes in the ionic strength and temperature causes the zeta potential of neutral liposomes to reverse sign. They proposed that the reversal of zeta potential is triggered by changes in the direction of the dipole connecting the negative charge of the phosphatidyl group and the positive charge of the choline group consisting the head group of a lipid molecule.

The study of the effect of drug-loading on the zeta potential of liposomes provides information regarding the drug-liposome interaction. Lawrence and others reported that the loading of polymyxin B, a polycationic antibiotic in negatively charged liposomes, results in the decrease of zeta potential, indicating electrostatic attraction between the positive drug and the negative lipid bilayer (43). That the highest drug-loading is found in negatively charged liposomes in comparison to positively charged and neutral liposomes further supports this electrostatic drug-liposome interaction. Beschiaschvili and Seelig investigated the

binding of a cyclic somatostatin analogue, a positively charged peptide, to negatively charged multilamellar liposomes (44). From the binding isotherm and the zeta-potential measurement, they were able to describe a partition equilibrium between the peptide and the negatively charged membrane with a surface-partition constant. They concluded that most of the peptide molecules are embedded in the headgroup region with little penetration into the lipid core.

The measurement of the zeta potential of liposomes provides valuable information relating to their *in vivo* performance because, in addition to size, the surface charge of liposomes is an important determinant of their clearance from the general circulation and their tissue disposition after parenteral administration. Large multilamellar liposomes are cleared from the circulation much more rapidly than small unilamellar liposomes. Among small unilamellar liposomes, however, those with a negative surface charge are cleared rapidly, but positively charged or uncharged liposomes remain in the circulation for longer periods (45). Rahman and his coworkers compared the pharmacological and therapeutic effects of adriamycin entrapped in positively charged and negatively charged liposomes in rats (46). They found that less cardiotoxicity was associated with the drug entrapped in the positively charged liposomes which exhibited lower *in vivo* uptake by cardiac tissue. When liposomes are employed to target drugs to lymph nodes, their surface charge has been shown to affect their lymphatic uptake from subcutaneous and intraperitoneal injection sites (47). Patel showed that negatively charged liposomes yield the highest localization in the lymph nodes, followed by positively charged and neutral ones. The drainage of negatively charged liposomes has also shown to be faster than that of positive liposomes after intraperitoneal administration (48).

SUMMARY

Zeta-potential measurement has long been recognized as an excellent tool for characterizing colloidal systems. Its practical significance stems from the fact that it allows the quantitation of the electrostatic repulsion between particles, which is one of the most important forces governing the behavior and physical stability of colloidal systems. In recent years, the concept of zeta potential has been applied to areas beyond classical colloidal sciences and industrial processes. Pharmaceutical sciences are the new fields to which the application of zeta potential has been extended. The expanding role of zeta potential in

these fields is attributable to the advance in modern instrumentation of zeta potential measurement, the rapid development of colloidal drug-delivery systems, and the emphasis on interdisciplinary basic research. While good correlation has been demonstrated for zeta potential and in vitro properties of colloidal drug-carrier systems, the understanding of the impact of zeta potential in organ distribution and in vivo clearance of these systems has been the focus of additional research efforts.

about the first edition . . .

"The depth and breadth of coverage...make it an excellent source for academic and special libraries supporting research programs in the health sciences, pharmacology, and chemical engineering."
—*American Reference Books Annual*

about the second edition . . .

Building on the success of the best-selling first edition, the *Encyclopedia of Pharmaceutical Technology, Second Edition* focuses on the discovery, development, design, manufacture, testing, regulation, and commercialization of drugs and dosage forms—emphasizing pharmaceuticals, pharmacokinetics, analytical chemistry, quality assurance, drug safety, and manufacturing processes.

New topics in the **Second Edition** include advertising and promotion of prescription and over-the-counter drug products...drug delivery via liquid inhalation...mixing and segregation in tumbling blenders...outsourcing of pharmaceuticals...paperless documentation systems...scale-up and postapproval changes...x-ray powder diffractometry...and more.

about the editors . . .

JAMES SWARBRICK is President of PharmaceuTech, Inc., Pinehurst, North Carolina, as well as Vice President for Scientific Affairs at aaiPharma, Inc., Wilmington, North Carolina. Prior to joining aaiPharma in 1993, he was Professor and Chairman of the Division of Pharmaceutics at the University of North Carolina at Chapel Hill School of Pharmacy. The coeditor of the first edition of the *Encyclopedia of Pharmaceutical Technology, Vols. 1-17 (with supplements)*, he is a Fellow of the American Association of Pharmaceutical Scientists (AAPS), the Academy of Pharmaceutical Sciences, the Royal Society of Chemistry, and the Royal Pharmaceutical Society of Great Britain. Dr. Swarbrick received the B.Pharm. degree (1960) from London University, England, the Ph.C. diploma (1961) from the Royal Pharmaceutical Society of Great Britain, and the Ph.D. degree (1964) in pharmaceutics and the D.Sc. degree (1972) in surface and physical chemistry from London University, England.
